Introduction

Genetic Approach: Mutagenesis Screen

Reverse Genetic Approach: Differential Display

Known Genes: Genetic Networks

Conclusion

Glossary

<i>Anoxia-inducible genes</i>	Genes that are activated by low oxygen.
<i>Anoxia tolerant</i>	Resistant to injury from anoxia.
<i>Differential display</i>	A technique used to screen for differentially expressed mRNA.
<i>Hypoxia-inducible factor (HIF1)</i>	A factor found to enhance the activation of transcription of the Epo gene as well as other genes by binding to DNA.
<i>Mutagenesis screen</i>	A screen for a phenotype after mutagenesis of genome.

This article addresses the environmental stresses of oxygen and glucose deprivation and their consequences, especially in the central nervous system and in sensitive organs in early life. Such stresses can be rather mild or moderate and can activate mechanisms that allow the organism or a specific tissue to adapt and survive the stress. More severe stresses may be injurious to the organism and may lead to cell death, tissue death, and ultimately death of the whole organism.

Introduction

It is clear from a large body of literature that organisms vary greatly in their response to lack of oxygen. Some, such as mammals, are generally susceptible to this stress, although mammalian newborns are more resistant to such a stress than adults, which have more differentiated organs and tissues. In addition, tissues within an organism, cells within an organ, and even cell types within a region of an organ can be differentially sensitive to the lack of oxygen and substrates. Consider and compare, for example, the tolerance to a lack of oxygen in muscle versus the brain, the hippocampal neurons versus the glial cells, and the CA1 layer versus the dentate gyrus.

Because the turtle is an organism that is extremely tolerant to oxygen deprivation, it has been used extensively and is an excellent animal model for the study of tolerance to oxygen deprivation. However, several problems inherent to this model have prevented major progress in understanding the basis of the turtle tolerance; for example, a genetic approach is precluded. Since the late 1980s, we have searched for a model in which multiple approaches can be used, including molecular and genetic techniques. In this search, we have found that *Drosophila melanogaster* is extremely tolerant to oxygen deprivation. It can resist, without apparent injury, several hours of complete oxygen deprivation or anoxia. Clearly the advantages of using *Drosophila* are multiple: (1) genetic approaches can be easily adapted and used, (2) there are hundreds of markers and mutations on the *Drosophila* chromosomes that facilitate mapping of mutations, (3) there are only three chromosomal pairs (the fourth is extremely small) in the *Drosophila* genome, (4) physiological, molecular biological, and genetic approaches are feasible in the fruit fly, and

(5) whole-fly studies including transgenic fly work is rather easily performed. We have therefore developed this model further and performed a considerable number of investigations using the fruit fly. We have used three different approaches to address the genetic basis of the response of the fruit fly to low or absent environmental oxygen. In this article, we summarize our findings to date using these different approaches.

Genetic Approach: Mutagenesis Screen

In order to perform a mutagenesis screen, we characterized the wild-type response to hypoxia using a number of behavioral and physiological assays. We first subjected flies to extremely low oxygen concentrations (0.01%) and studied their physiological and behavioral responses during anoxia and after the start of reoxygenation. Flies were first exposed to anoxia (complete lack of oxygen) for periods of 5–240 min. After 1–2 min in anoxia, *Drosophila* lost coordination, fell down, and became motionless. However, they tolerated a complete nitrogen atmosphere for up to 4 h, following which they recovered. In addition, a nonlinear relation existed between the time spent in anoxia and the time to recovery. Extracellular recordings from flight muscles in response to giant fiber stimulation revealed complete recovery of muscle-evoked response, a response that was totally absent during anoxia (Figure 1). Mean oxygen consumption per gram of tissue was substantially reduced in low oxygen concentrations (20% of control). We concluded from these studies that (1) *D. melanogaster* is very resistant to anoxia and can be useful in the study of mechanisms of anoxia tolerance and (2) the profound decline in metabolic rate during periods of low environmental oxygen levels contributes to the survival of *Drosophila*.

Genetic Screen for Anoxia-Sensitive Mutants

We focused our screen for mutations on the X chromosome because the mutant phenotype can be observed in the immediate next generation without the need for single-pair matings. Mutagenized (x ray, 4000 rad) C-S males, which were crossed to attached-X females [*c(1)yw*], transmitted their X chromosome to the male offspring. More than 20,000 flies, carrying mutagenized chromosomes, were screened. A threshold, which is close to the ninety-sixth percentile of the wild-type distribution, was used to identify and isolate mutants. Eight mutations were identified and found to alter the distribution of recovery times profoundly (Figure 2). The marked delay in recovery after anoxia displayed by these mutant flies suggested that they were much more sensitive to a lack of oxygen. We have therefore termed these mutants *hypnos* to describe (1) their sensitivity to oxygen deprivation (*hypoxia*, *anoxia*, sensitive) and (2) the phenotype of delayed recovery and sleepiness.

Genetic Mapping

The mapping of the induced mutations was performed with X-chromosomal markers and complementation tests. Several markers were used, including *y*, *cv*, *v*, *f*, *car*, and *su(f)*. Complementation testing was done on several X-linked recessive mutations obtained. A number of these mutations were mapped, and they seem to be spread in a number of locations on the X chromosome. For example, one of them is on the right side of *f* (*forked*), another is between *y* and *cv*, and yet another is between *cv* and *f*. One of the mutations has been refined in terms of the mapping, and we have localized it to a rather narrow region between *y* and *cv* using deficiencies.

Figure 1 Effect of anoxia on evoked dorsal longitudinal muscle (DLM) response. a, DLM response; b, lack of DLM response during anoxia, even after a 10-fold increase in duration and intensity of stimulus.

Figure 2 Distribution of cumulative frequency of recovery time in wild-type (C-S) and mutant flies.

Hypnos Mutations Affect Central Nervous System Recovery from Anoxia

The behavioral testing, which showed delayed recovery from anoxia, led us to believe that the *hypnos* mutations affected the central nervous system. To further our understanding of the mutations we obtained, we directly examined the effect of these mutations on central nervous system function. Identified neurons that can be studied electrophysiologically in *Drosophila* are those of the Giant Fiber system. The stimulation of eye neurons, using low voltages, evoked spikes in the dorsal longitudinal muscle (DLM) with a long latency (4 ms). Experiments were carried out in three of the eight mutations (*hypnos*^{2^{PL}}, *Hypnos*^{1^N}) and on wild-type flies. In one mutant (*hypnos*^{2^P}), which had a severe phenotype, long-latency-evoked potentials could not be obtained, irrespective of the voltage and duration used. Flies having an allele of this locus (*hypnos*^{2^L}) or with the other severe mutation (*Hypnos*^{1^N}) had a baseline long-latency recording that was similar to that of C-S flies. However, during recovery, whereas the DLM of wild-type flies started to respond after 2 min into recovery, flies with these two mutations had a much longer time to the first evoked potential, with some mutant flies requiring up to 25–30 min for the first evoked response to occur.

The current genetic screen is not saturated and is restricted to the X chromosome. However, we had to screen more than 20,000 mutagenized flies to obtain

hits in the same locus (two loci hit twice). This suggests that a limited number of genes can be mutated in *Drosophila* to produce similar phenotypes. Because these mutations profoundly disrupt the recovery from anoxia, we believe that this approach can be used effectively to dissect the genetic basis of responses to low oxygen.

Reverse Genetic Approach: Differential Display

The idea behind the reverse genetic approach is to identify those genes that are differentially expressed during a condition or a stress. In our case, we used very low levels of oxygen and assessed whether there were up- or downregulated mRNA during the period of hypoxia compared to naive or nonexposed flies. RNA differential display was performed as described by Liang and Pardee, with minor modifications. The DNase-treated total RNA was used for reverse transcription. The cDNAs generated from polymerase chain reaction (PCR) were blotted; the bands of interest were located, cut out, and reamplified and cloned into the PCRII vector. To determine the relative size of selected candidate transcripts, northern analysis was performed. To obtain full-length cDNA, we screened the fly head λ gt11 library using the cDNA fragments that were isolated from the differential display. In addition, 5' and 3' rapid amplification of cDNA ends (RACE) PCR were also performed.

Figure 3 *In situ* hybridization of gene *fau*. a, Polytene chromosomes; b, In the central nervous system of *Drosophila* (antisense); c, In the central nervous system of *Drosophila* (sense).

In addition to the cloning of this particular gene, we have localized it on the X chromosome using *in situ* hybridization. This is usually helpful for developing mutants with P elements and therefore examines the role of that particular gene in the context of the whole organism or cell (Figure 3a). Furthermore, we have also localized the mRNA of *fau* (*fly*, *anoxia*, *upregulated*) in the central nervous system of the fly as seen in Figure 3b–c. This figure shows that the *fau* mRNA is localized in certain areas such as the cortex.

Gene Expression Following Anoxia

The data from our differential display and northern analysis clearly show that certain genes were up-regulated while others were downregulated during anoxia. From the PCR reactions, we found that the expression level of several transcripts was visibly affected by anoxia. We have selected one transcript that was markedly upregulated to focus on and study. We termed this transcript *fau*. The *fau* cDNA and its deduced protein sequence have several interesting and potentially important characteristics. Seven ATTT motifs, for example, were found in its 3' UTR. The AUUUA motifs reportedly play a role in the stability and translocation of transient mRNAs. Therefore, the ATTT motifs found in *fau* cDNA may play a similar role in hypoxia-induced mRNAs and could regulate their expression. In addition, there are two (TA)_{9–10} stretches in the 3' UTR of this cDNA. Although their function is not clear, taken together, these unique sequences in the 3' UTR with high GC content in the *fau* cDNA open reading frame may define a functional anatomy of transient or stress-induced mRNAs. The deduced protein sequence of *fau* cDNA also has a high

number of phosphorylation sites, which makes it an appropriate substrate for phosphorylation. It is possible then that the *fau* protein can participate in metabolic pathways. Because our computerized search did not reveal a significant homology with published sequences, the deduced *fau* protein is most likely a novel phosphorylated one.

Role of *fau* Protein

In spite of the fact that we have no direct evidence that this gene is involved in anoxic survival in *D. melanogaster*, we believe that *fau* plays an important role during anoxic stress based on the following. (1) The expression of this gene was upregulated when the overall reduction of protein synthesis in general occurs during the lack of oxygen. (2) The overexpression of *fau* in transgenic flies prolonged their recovery from anoxia. (3) The putative protein encoded by this gene is probably highly regulated by phosphorylation, suggesting that it is active during O₂ deprivation. (4) The richness of the AUUU motif in 3' UTR of this mRNA could make it a transient one, with a relevant function during O₂ deprivation.

There is a debate in the literature as to whether cells, particularly nerve cells, die from anoxia via mechanisms that induce active processes or via others that shut off pathways and protein synthesis. It is clear from a number of studies that survival and adaptation during anoxia or cell death resulting from anoxia involves the synthesis of proteins, although the overall net balance is a marked reduction in protein synthesis. Numerous studies, for example, have shown that there are genes that are selectively turned on or upregulated by oxygen deprivation. Our previous data have demonstrated that

anoxia remarkably upregulated the expression of a heat shock protein (HSP70) gene, whereas it suppressed the expression of ubiquitin 4 in the fruit fly. A hypoxia-inducible factor 1 (HIF-1) was found to enhance the activation of transcription of the Epo gene as well as other genes by binding to DNA. Hence, we believe that during anoxic stress-tolerant cells such as those in *Drosophila* depress their oxygen consumption and requirements by lowering the metabolic rate and reducing protein synthesis. However, a protein hierarchy within these cells exists for survival; that is, there are certain proteins that are either newly induced or protected from proteolysis, whereas the majority of proteins have a decreased or negligible synthetic rate and are downregulated. It is possible then that proteins such as HIF are overly expressed in order to render cells better adapted to lack of oxygen. However, why would an increase Fau protein occur during hypoxia if an increase in this protein increases by itself the sensitivity to anoxia? At present we cannot be certain because we do not have a comprehensive picture of the various genes and gene products that are important during such stress. For example, we do not know the relation between Fau and other proteins.

Known Genes: Genetic Networks

This approach relies on genes known to be important in the mammal's response to oxygen deprivation. This approach then aims at cloning and studying fruit flies in order to better delineate the genetic pathways and molecular mechanisms underlying the resistance of fruit flies to lack of oxygen. It is assumed that this challenge is better met in organisms such as *Drosophila* than in mammals because of the flexibility and feasibility of molecular approaches in this organism.

Expression of Known Genes

We analyzed mRNA expression of heat shock proteins (HSP26 and HSP70), ubiquitins (UB, UB3, and UB4), cytochrome oxidase I (COX1), and superoxide dismutase (SOD) using slot-blot analysis. The expression of HSP genes, especially HSP70, was remarkably upregulated (up to 1000-fold), whereas those of UB4 and COX1 were downregulated (10–60%) in response to the anoxic stress. The expression of UB3 gene was upregulated by 1.5 times, and the expression of the SOD gene was not significantly affected. In response to heat shock stress, the expression of HSP genes increased by up to several thousandfold, the expression of UB genes increased modestly (23–91%), and the expression of SOD and COX1 genes was reduced by approximately 25%. Furthermore, the expression patterns of HSP genes under anoxia and heat shock

were clearly different. The expression of HSP genes peaked by 15 min into anoxia and then declined but stayed above the baseline. In contrast, their expression increased as a function of time during heat exposure.

Known Pathways

One of the transcription factors that has been shown to be crucial for sensing the lack of oxygen is HIF1. This transcription factor has two subunits and, when they dimerize, they induce the expression of a number of genes, including *Nitric oxide synthase* and *Vascular endothelial growth factor* (VEGF). We and other investigators have cloned the HIF1 β -subunit from *Drosophila*. The α -subunit has been cloned and both the α - and the β -subunits have relatively high homology to those of mammals. At present, we are examining the role of these genes in *Drosophila*. In addition, the approach here aims at examining the pathways that these genes are involved in.

Conclusion

Stress as defined in this article involves the lack of oxygen. Generally, this type of stress has been equated with a pathophysiological signal, that is, with a condition that can lead to cell injury or cell death. However, it is apparent that, although this can certainly be true, especially in moderate or severe stress, it may not be so in milder stresses. In addition, the timing of the stress is exceedingly important. Even though it can be severe, hypoxic conditions in development or during organ formation can be tantamount to signals that are important in the induction of certain genes such as VEGF, which is crucial for organ development and embryogenesis. A failure of response to hypoxia in knockouts such as the HIF knockout can lead to the failure of embryogenesis and demise of the embryo. Indeed, fetal demise is observed in knockouts of both subunits of HIF and in that of VEGF.

Glossary

<i>Chromosome puff</i>	An expansion or decomposition of a polytene chromosome band indicative of altered chromatin structure and high-level transcriptional activity.
<i>P element</i>	The class II DNA transposable element which was engineered to carry modified or foreign genes into the <i>Drosophila</i> genome and allow germ-line transformation.
<i>Polytene chromosome</i>	Lengthwise alignment and coherence of the multiple copies of the chromosome in specialized polyploid cells which allows for light microscope visualization of banding patterns.

Powerful genetic and molecular tools combined with ease of culture have made *Drosophila* a leading model organism for studies of stress. For example, stress response gene induction was first discovered in the early 1960s in *Drosophila* as a characteristic pattern of polytene chromosome puffs in cells subjected to heat or oxidative stress. In the late 1970s *Drosophila* hsp genes were among the first eukaryotic genes cloned. The development of P element-mediated germ-line transformation in 1982 made *Drosophila* one of the first transgenic multicellular organisms. These and other discoveries led to pioneering and ongoing functional studies of stress responses and stress tolerance. A subset of the vast literature on *Drosophila* stress studies is discussed.

Stress Response Genes Including the hsp's Are Induced in Response to Heat and Other Stresses and Can Confer Stress Tolerance

In *Drosophila* six major hsp's are induced in response to heat stress, hsp83, –70, –27, –26, –23, and –22, and several additional proteins exhibit smaller inductions. Hsp83 is constitutively expressed and upregulated severalfold during heat stress. Hsp83 is a member of the *hsp90* gene family which is highly conserved through evolution. Hsp83 functions include regulating the activity of proteins in signal transduction pathways whose functions in turn involve conformational changes. Hsp70 is the most highly conserved through

evolution, and in *Drosophila* is induced over 1000-fold during heat stress. Based on studies of hsp70 family members in *Drosophila* and other organisms, hsp70 is thought to decrease protein denaturation and aggregation, facilitate refolding of partly denatured proteins, facilitate entry of damaged proteins into proteolytic pathways, and protect the organism from additional stress: experimental induction of hsp70 transgenes can confer thermotolerance to cultured *Drosophila* cells, and *Drosophila* transgenic for extra copies of hsp70 exhibit increased thermotolerance at certain stages of development. The *Drosophila* small hsps (–22, –23, –26, and –27) are related to each other and to small hsps from other organisms by a conserved α -crystallin protein domain and also appear to be molecular chaperones involved in stress resistance. The *hsr-omega* gene is also induced by heat stress, but produces no detectable protein product and may function in stress tolerance by an unusual mechanism.

The mechanism of *Drosophila* heat shock gene transcriptional induction by heat stress has been studied in detail, particularly for the *hsp70* gene. Binding sites for the GAGA and TBP (TATA-binding protein) transcription factors and other promoter sequences generate a primed promoter chromatin structure in unstressed cells. This structure includes a transcriptionally engaged RNA polymerase paused ~25 nucleotides downstream of the start site for transcription. This arrangement is thought to facilitate rapid induction upon stress. Heat stress causes trimerization and activation of the constitutively expressed heat-shock transcription factor (HSF), which is required for heat-shock gene induction. Heat-shock transcription factor binds to the heat shock response elements (HSEs) which are evolutionarily conserved promoter elements essential for transcriptional induction during heat stress. Heat-shock transcription factor binding to the HSEs results in release of paused polymerase and high-level transcription of the heat-shock gene.

Induction of the hsps also involves posttranscriptional regulation, as heat-shock gene RNAs are preferentially translated in heat-stressed cells and are more stable during heat stress.

Different Environmental Stresses or Laboratory Selection for Altered Stress Resistance Can Affect Gene Allele Frequencies Including Stress Response Genes

Drosophila isolated from different natural stress environments often exhibit correlated stress response phenotypes. For example, *Drosophila* isolated from hotter environments are generally more resistant to thermal stress. Similarly, laboratory populations of

Drosophila selected over many generations for survival of a particular stress can exhibit increased resistance to that stress and exhibit correlated changes in allele frequencies in specific stress-response genes. Studies of this type provide a model for the relationship between environmental stress and evolution.

Drosophila Mounts an Immune Response to Biotic Stress

The response to septic injury includes rapid induction of antibacterial and antifungal peptides. Induction is mediated in part by the evolutionarily conserved Toll/Dorsal signal transduction pathway, which is homologous to the interleukin-1 receptor NF- κ B immune response pathway in mammals.

Life Span and Aging Phenotypes Correlate with Stress Resistance and a Characteristic Pattern of hsp Expression

Drosophila populations can be genetically selected for increased life span, and these populations exhibit increased resistance to various stresses, including desiccation, starvation, and oxidative damage. Conversely, selection for increased resistance to specific stresses can result in increased life span. A subset of hsps are induced during aging, primarily hsp22 and hsp70. Mild heat stress which induces hsps can cause small increases in the life span of *Drosophila*. Slightly larger heat-induced increases in life span were achieved in *Drosophila* transgenic for extra copies of the *hsp70* gene. Finally, oxidative stress resistance and aging phenotypes have been altered in *Drosophila* transgenic for additional (or modified) oxygen radical defense genes, such as *catalase* and *superoxide dismutase*.

Stress and Drug Addiction

Clinical Evidence

Animal Studies

Effects of Drug Abuse on Stress Responses

Neurobiological Mechanisms

Treatment Implications

Glossary

<i>Addiction</i>	A chronically relapsing neurobiological disease characterized by an inability to control drug use.
<i>Craving</i>	An intense, consuming, and often uncontrollable desire to use a drug.
<i>Neuroplasticity</i>	The ability of the brain to physically change in response to stimuli such as drugs.
<i>Relapse</i>	The recurrence of drug use after a period of drug abstinence.
<i>Withdrawal</i>	A broad range of adverse symptoms that emerge on the termination or reduction of drug use.

Stress and Drug Addiction

Drug addiction is a chronically relapsing condition that is characterized by an inability to self-regulate drug consumption. In an addicted individual, drug use is compulsive and occurs in spite of negative social, legal, financial, and medical consequences. Despite its prevalence and tremendous cost to society, little progress has been made in the development of effective addiction treatment strategies. One of the issues that makes addiction so difficult to treat is that not all addicts use drugs for exactly the same

reasons. Thus, the factors that contribute to drug use by one individual may be quite different from those that underlie drug self-administration by another. In many individuals, drug use is a stress-driven behavior. This is especially problematic because the life of a drug addict is a particularly stressful one; even though many individuals initially turn to drugs in order to help them cope with stress, drug use by itself can generate and/or aggravate stress responses. The result of this circular relationship between stress and drug use appears to be a vicious cycle within which the onset of stress promotes drug use, which in turn generates more stress and therefore leads to further drug-seeking behavior. Breaking this self-perpetuating cycle by minimizing the influence of stress will probably provide a key to the successful treatment of many drug addicts.

People use drugs because of the effects that they have on the brain. Acutely, drugs produce their euphoric effects through the activation of the neural circuits that underlie natural reward. Such effects tend to offset the negative feelings typically associated with stress. With repeated drug exposure, changes in this neurocircuitry begin to emerge such that the brain of a drug addict is functionally different from that of a non-drug user or someone who only occasionally uses drugs. Significantly, when a drug is used repeatedly, the incentives and neurobiological events that drive drug use change such that the drug user enjoys the drug less but needs the drug more. These changes in brain function that emerge with repeated drug use are collectively referred to as neuroplasticity and appear to be long-lasting, if not permanent. The consequence of such long-lasting neuroplasticity is a diseaselike condition that is associated with a high risk for relapse in many individuals. For this reason, understanding how neuroplasticity that is pathogenic for addiction develops and is expressed is critical for the prevention and treatment of the condition. Similar to its role in the addiction cycle, the

involvement of stress in addiction-related neuroplasticity is bidirectional. Stress promotes the onset of drug-induced neuroplasticity, the expression of which includes aggravated behavioral and hormonal stress responses.

Clinical Evidence

Clinical evidence for a role for stress in drug addiction is largely anecdotal and correlative. In general, stress is cited as a causative factor for drug use, and the inability to effectively cope with stress is predictive of drug relapse. In addition, there is a high incidence of stress-related comorbidity, including posttraumatic stress disorder (PTSD), panic attacks, and depression in drug-dependent populations. For example, it has been reported that up to 43% of cocaine-dependent individuals meet the *Diagnostic and Statistical Manual of Mental Disorders* (3rd edn. rev.; DSM III-R) criteria for lifetime PTSD. In one study, 95.5% of subjects with concurrent PTSD and cocaine dependence reported a functional relationship between cocaine use and their PTSD symptoms, with 86.4% indicating that their PTSD symptoms worsened with drug use.

More direct evidence that stress can lead to drug use is provided by clinical laboratory studies demonstrating that the personalized stress imagery scripts can increase subjective measures of craving for cocaine and alcohol in recovering addicts. In fact, these studies have shown that scripts describing stressful events can be just as effective at eliciting drug craving as scripts describing actual drug use. The ability to directly assess stress-induced craving in human addicts within a laboratory setting should provide a useful tool for testing the effectiveness of novel treatment approaches aimed at preventing stressor-induced drug use.

Animal Studies

The study of drug abuse has relied heavily on preclinical animal research. In particular, drug self-administration procedures in which rats are surgically implanted with intravenous catheters and required to perform a behavioral task, such as pressing a response lever, in order to receive drug infusions have been valuable for the preclinical study of drug abuse and addiction. The validity of such procedures arises from the observation that, with few exceptions, drugs that are abused by humans are also self-administered by rats. Variations of the self-administration procedure have been used to define a role for stress in different aspects of the addiction process. In particular, research has focused on the effects of stressors on the acquisition, escalation, and reinstatement of

drug-seeking behavior. A brief summary of this research is provided next.

Acquisition

Not everyone who tries a drug for the first time will like it and will start using the drug on a regular basis. Individual differences in initial responsiveness to drugs exist and can be influenced by a number of variables. Some individuals are genetically predisposed toward drug abuse, whereas others are influenced by environmental factors such as stress. It is likely that for many, individual susceptibility to addiction arises from a complex interplay among genes, drug effects, and environment such that the genetic potential for addiction is realized only if the drug is used in the wrong environmental context.

Preclinically, factors that increase the likelihood that drug use will be initiated can be studied using acquisition self-administration models in which predisposition to engage in drug use is defined according to how readily drug-naïve subjects acquire the behavior of drug self-administration. Using such models, it has been reported that a variety of stressful stimuli ranging from very basic stressors (such as repeated tail pinch) to more complex stressors (such as social defeat) facilitate the acquisition of drug self-administration by rats. These effects of stress do not appear to be short-lived. In fact, it has been reported that when rats are exposed to a stressor during the first weeks of life (e.g., daily isolation) more rapid acquisition of drug self-administration can be observed months later during adulthood, suggesting that the onset of stress, especially at critical phases of life, may permanently increase individual susceptibility to drug addiction. Interestingly, it is not just stress but the ability to control stress that is important for its effects on acquisition. Rats exposed to electric foot-shock stress acquire cocaine self-administration at lower dose than nonshocked controls when they are unable to control shock delivery but not when the same amount of shock is delivered under response-contingent conditions. These findings parallel clinical reports that it is not the onset of stress *per se* that predicts drug use but rather the coping strategy that is used when an individual is confronted with a stressor. Understanding how stress serves as a determinant of the initiation of drug use will permit the identification of populations that are at risk for addiction and should aid efforts to prevent drug abuse.

Escalation

Just because someone uses a drug regularly does not mean that that person is addicted. It is the loss of control over drug use and its negative impact on

other facets of a drug user's life that define addiction. This aspect of drug addiction has been studied using rodent drug self-administration models in which progressively escalating patterns of drug intake emerge when daily access to a drug is prolonged. The onset of escalating use patterns is thought to reflect the transition from controlled drug use to out-of-control drug addiction. For this reason, further characterization of the variables that promote escalating self-administration patterns in rodents should provide insight into factors that accelerate the onset of drug addiction. Recently, our laboratory has begun to examine the impact of chronic stress delivered across an extended period of ongoing cocaine self-administration. To date, our studies have shown that exposure to stress at the time of daily cocaine self-administration progressively escalates drug intake over a 14-day period, suggesting that, like prior exposure to cocaine, repeated stress can accelerate the onset of addiction. Significantly, these findings imply that in addition to acutely generating drug use, stress can aggravate addiction by promoting drug-induced neuroplasticity.

Reinstatement

In drug addicts, craving, or the intense desire to use a drug, typically precedes drug use. The onset of craving is often unpredictable and can suddenly occur even after months or years of drug abstinence, making it a formidable obstacle to the effective long-term management of drug addiction. Drug craving can be studied preclinically using reinstatement self-administration procedures in which the abilities of various stimuli to reinstate extinguished drug-seeking behavior are examined. With these procedures, drug self-administration is extinguished by replacing the drug with an inert substance. As a result, responding previously maintained by presentation of the drug declines. The restoration or reinstatement of extinguished behavior under various experimental stimuli is thought to reflect the onset of craving for that drug and therefore can be used to identify the risk factors for drug relapse. Using such procedures, it has been demonstrated that acute exposure to stressors can reinstate responding previously reinforced by a variety of abused drugs including cocaine, ethanol, heroin, and nicotine without increasing responding not previously associated with drug delivery. These findings parallel those from clinical studies showing that subjective stress imagery can increase measures of drug craving in recovering addicts and suggest that the inclusion of pharmacological and behavioral strategies aimed at reducing stress during drug abstinence is probably critical to the success of any addiction treatment program.

Effects of Drug Abuse on Stress Responses

In addition to acting as a causative factor for drug-seeking behavior, stress also emerges as a consequence of drug use. It is well known that for most drugs of abuse, intense stress and anxiety are prominent features of acute drug withdrawal. In animal studies, these withdrawal symptoms can be observed as exaggerated anxiety-like behaviors measured using a variety of behavioral tests following withdrawal from repeated drug exposure. Significantly, altered anxiety responses appear to persist long after other acute withdrawal symptoms dissipate. These augmented anxiety-like responses during late withdrawal probably translate into increased susceptibility to drug relapse during periods of stress. One way to examine the effects of prior drug use on relapse is to compare stressor-induced reinstatement during withdrawal in rats with different histories of drug exposure. When rats have a history of self-administering greater amounts of drug, they also display higher levels of reinstatement in response to stress, suggesting that the amount of prior drug use can alter responsiveness to stress in a way that contributes to further drug-seeking behavior. These findings are paralleled by the results of clinical studies showing that stress-induced cravings, anxiety, and physiological responses in abstinent cocaine users are augmented in individuals with a history of high-frequency cocaine use compared to individuals with a history of using the drug less frequently. Our own data indicate that the behavioral responses to stressors are not simply exaggerated as a consequence of drug self-administration but, rather, are qualitatively different such that rats with a history of cocaine self-administration appear to be more assertive when confronted with a stressful situation, possibly reflecting a maladaptive coping strategy during stress that may result from drug use.

Neurobiological Mechanisms

Like all factors that influence drug-seeking behavior, stressors exert their effects on drug use by altering the activity of the neurobiological systems within the brain that underlie motivated behavior. In particular, a critical role for a pathway in the brain consisting of nerve projections from the medial prefrontal cortex that release the amino acid neurotransmitter glutamate into the nucleus accumbens has been identified for drug-seeking behavior. This neural subcircuit is closely modulated by the neurotransmitter dopamine, released from nerves that originate in the ventral tegmental area (VTA) of the midbrain. Like other stimuli that acutely generate drug use, stress provokes

drug-seeking behavior through the activation of this pathway. The mechanism through which this activation occurs during stress is not entirely clear, but it appears to require the stimulation of dopaminergic neurons in the VTA that project to the medial prefrontal cortex and almost certainly involves the neuropeptide corticotropin releasing hormone (CRH). Significantly, stress can intensify the responsiveness of this motivational pathway to subsequent stimulation by inducing a form of cellular neuroplasticity in dopaminergic cells in the VTA called long-term potentiation (LTP), thereby increasing vulnerability to the effects of abused drugs.

Corticotropin Releasing Hormone

In addition to its role as an initiator of the hormonal stress response through its actions in the pituitary gland, CRH exerts its effects within the brain, where it functions as a neuropeptide mediator of stress-related behavioral responses and anxiety. CRH administered directly into a number of brain regions, including the VTA, reinstates extinguished drug-seeking behavior, whereas CRH antagonists prevent stress-induced reinstatement. The exact mechanism through which CRH stimulates dopamine cells in the VTA is unclear, but it appears to require the association of CRH with its binding protein and the activation of a specific subtype of the CRH receptor, the CRH₂ receptor, which in turn facilitates cellular activation by the neurotransmitter glutamate. The likely role for CRH as a mediator of stress-induced drug-seeking behavior makes the peptide an obvious target for the development of pharmacotherapy aimed at promoting drug abstinence by preventing relapse during periods of stress. Although promising, clinical evaluation of the usefulness of drugs that interfere with the actions of CRH awaits the availability of selective nonpeptide CRH-receptor-blocking drugs that can readily penetrate the blood-brain barrier to reach sites of CRH action in the brain.

Glucocorticoids

Although the ability of acute stress to precipitate drug craving and use is problematic for addicts, it is chronic stress that can have an especially deleterious impact on the addiction process by producing or facilitating neuroplasticity that is pathogenic for addiction. Whereas the acute effects of stress on drug-seeking behavior appear to be mediated primarily through the actions of CRH in the brain, many of the effects of chronic stress on drug use appear to involve the release of glucocorticoid hormones from the adrenal gland. Glucocorticoids (such as cortisol in humans and corticosterone in rats) are critical mediators of

the physiological and behavioral responses that enable an organism to adapt to and cope with stress. Such responses are beneficial for short-term adaptation to stressful stimuli, but, with constant activation, they can be detrimental to an organism, a consequence of chronic stress referred to as allostatic load. These allostatic effects appear to include adaptations in the motivational neurocircuitry of the brain that promote illicit drug use. Although glucocorticoids alone are capable of producing addiction-related neuroplasticity, it appears that in many cases these hormones work in concert with other stress-related molecules such as CRH to influence the addiction process. It is likely that many such interactions occur in the VTA, where stressor-induced neuroplasticity involving dopamine cells appears to be mediated by CRH and may require glucocorticoid receptor activation. Further research is needed to determine whether glucocorticoids and their receptors are viable targets for the pharmacotherapeutic management of drug addiction. A summary of one putative neurobiological pathway through which stress influences drug-seeking behavior is provided in [Figure 1](#).

Treatment Implications

The recognition that stress is a key contributor to drug abuse and addiction should highlight the need for the development and implementation of novel therapeutic strategies aimed at minimizing the contribution of stress to the addiction process, especially in subpopulations of addicts whose drug use is stress-driven. Identifying which addicts will benefit most from such approaches poses a challenge to drug-dependence treatment providers and will probably require the establishment of new assessment tools that permit the determination of the role of stress in drug use on an individual basis. Although available, cognitive and behavioral therapies aimed at helping recovering addicts manage their stress are underused and understudied. Further, many drugs that are traditionally used for the treatment of stress-related psychiatric conditions (e.g., antidepressants and benzodiazepines) are not commonly prescribed to treat addiction and, in many cases, are avoided even though they may be beneficial if used properly in the right individuals. The eventual development and approval of new drugs that block the actions of CRH in the brain will, it is hoped, provide important tools for the management of drug addiction. At the same time, basic preclinical research must continue to examine the neurobiological mechanisms through which stress influences drug addiction so that new targets (e.g., the orexins/hypocretins) can be discovered and more effective drugs can be developed.

Figure 1 One putative neurobiological pathway through which stressful stimuli may influence drug-seeking behavior and addiction. The results of recent animal studies indicate that stressful stimuli increase brain corticotropin releasing hormone (CRH) levels, which, in concert with elevated glucocorticoids, exert effects on cells in the ventral tegmental area of the brain to increase dopaminergic neurotransmission in the medial prefrontal cortex and nucleus accumbens and facilitate the activity of neurocircuitry that underlies motivation and natural reward.

avoidance of stimuli associated with the traumatic stressor, numbing of emotional responsiveness, and increased arousal. A study in which the subjects are identified and then followed forward in time. A clinical trial in which investigators randomly assign eligible subjects to groups to receive or not receive one or more interventions that are being tested or compared. It is a design widely considered reliable because it eliminates a variety of biases that compromise the validity of medical research.

A class of antidepressants that increase serotonin levels by inhibiting serotonin reuptake.

Glossary

*Cognitive-
behavioral
treatment*

A psychological treatment involving the modification of maladaptive thinking patterns and systematic exposure to anxiogenic stimuli until the associated anxiety subsides.

*Earthquake
epicenter
Earthquakes*

The point on Earth's surface directly above the focus of an earthquake.

Natural phenomena that involve abrupt shaking and vibration of the Earth's crust caused by the release of stress accumulated along geologic faults or by volcanic activity.

*Longitudinal
study*

A study that involves observations of the same items over a period of time.

*Posttraumatic
stress disorder
(PTSD)*

An anxiety disorder that develops after exposure to a traumatic stressor and involves symptoms of persistent reexperiencing of the traumatic stressor,

Earthquakes are common natural disasters that can cause widespread devastation and casualties and expose large numbers of people to bereavement, injury, loss of property, homelessness, and displacement. Considering only the earthquakes that killed more than 1000 people, approximately 1.8 million people died in 108 earthquakes in the twentieth century. Earthquakes often cause greater devastation and casualties in developing countries because of the generally low quality of buildings, lack of disaster preparedness, and inadequate rescue and relief efforts. Indeed, 91 of the 108 major earthquakes (with a death toll over 1000) in the twentieth century occurred in developing countries, accounting for 83% of 1.8 million deaths worldwide.

Exposure to earthquakes is associated with psychological distress, PTSD, and depression. Although the extent of devastation and casualties caused by a disaster is thought to relate to the severity of the

subsequent psychological distress, recent studies suggest that even earthquakes of relatively low magnitude or those that cause limited devastation can lead to extensive posttraumatic stress reactions. Consequently, earthquakes pose a mental health hazard not only in developing countries but also in industrialized countries, even when people suffer relatively less damage and fewer casualties.

Psychological Consequences

The Earthquake Experience

The violent tremors of a major earthquake can cause serious damage to solid structures. People may be killed, injured, trapped under rubble or may witness the injury or death of others and the loss of their property. The impact of the earthquake experience is associated with many factors, including earthquake characteristics (magnitude, duration, etc.), proximity to the epicenter of the earthquake, strength of the buildings, and the nature of the ground that supports the buildings.

Fear and helplessness are among the most common emotional reactions that people experience during an earthquake. Intense fear during earthquakes has also been linked to deaths from cardiac arrests and extreme behaviors that reflect panic (e.g., jumping from the window of a tall building).

Acute Phase

In the first few days and weeks after a major earthquake, the affected communities focus on rescuing those who have been trapped under rubble, caring for the injured, assessing the extent of the damage, and planning the management of the problems caused by the earthquake. Bereaved survivors face the task of burying their loved ones, and homeless survivors seek temporary accommodation. Ongoing aftershocks may cause further damage and casualties.

In the acute phase, the regular activities of the affected communities may be disrupted. Some survivors avoid entering their relatively undamaged or mildly damaged homes either because they are uncertain about their safety or because of fear of further earthquakes. Governments and relief organizations often set up tent camps and prefabricated housing sites to accommodate homeless survivors. In addition, the fearful anticipation of further earthquakes is prevalent.

Relatively little is known about the psychological status of survivors in the acute-phase aftermath of a major earthquake. The few existing studies that involved assessments 1–4 weeks postearthquake were based on convenience or clinical samples and reported

increased rates of symptoms of acute stress disorder (dissociative symptoms, reexperiencing, avoidance of trauma reminders, and anxiety or increased arousal) and depression. In cases in which the earthquake caused casualties, the acute phase may also involve bereavement reactions.

Medium-Term Effects

In the year that follows a major disaster, many survivors face the difficult task of coming to terms with bereavement, injury, material loss, homelessness, disruption of activities, relocation, and other earthquake-related stressors. Those living in shelters (tents, makeshift barracks, and prefabricated houses) may be deprived of basic needs and face disruption in their daily routine. Ongoing aftershocks may cause additional traumatic stress.

Studies examining the psychological status of adult and child survivors 1–18 months postearthquake show considerable variation in methodology (e.g., sampling, severity of earthquake exposure and related devastation, assessment instruments, and time between the earthquake and assessment) and, consequently, in the reported rates of psychiatric problems. Most studies (Table 1) reported high rates of PTSD and depression among the survivors. In addition, although little is known about the incidence of other psychiatric disorders in earthquake survivors, there is evidence that earthquakes may lead to increased rates of generalized anxiety disorder and alcohol abuse/dependence. The psychological effects of earthquakes

Table 1 Range of estimated rates of PTSD and major depression^a

Type of sample ^b	PTSD ^c (%)	Major depression ^c (%)
Probability or consecutive	2–43	7–52
Convenience	9–95	13–42
Clinical	63–74	22–42

^aPTSD, posttraumatic stress disorder.

^bIn probability sampling there is random selection of study subjects, thus ensuring that each member of the population has equal probabilities of being chosen. In consecutive sampling, each household is targeted for assessment within a particular temporary housing site (tent-camp or prefabricated housing site) in the disaster region. In convenience sampling, the selection of subjects is based on easy availability and/or accessibility. In clinical sampling, the participants are drawn from among patients or treatment-seekers.

^cThe wide range of estimated reported rates mainly reflects differences in methodology (sampling, assessment instruments, time lapse between earthquake and assessment, etc.) and in the severity of the earthquake that the subjects of each study experienced.

may be less severe in professional rescuers, possibly because they tend to be more psychologically prepared for disasters and their consequences.

Long-Term Effects

Relatively few studies have examined the psychological status of survivors beyond 18 months post-earthquake. In a prospective cohort study based on survivors with high exposure to the 1989 earthquake in Armenia, the rates of PTSD 18 and 54 months after the disaster were 87% and 73%, respectively. Although symptoms of depression tended to subside over time, the severity of PTSD in survivors with high earthquake exposure did not show a significant reduction. In another study following the 1989 Newcastle earthquake, 48% of the survivors who had PTSD at 6 months postearthquake still had PTSD 2 years later. Earthquake-related morbidity showed a decline in the months after the earthquake, but stabilized at approximately 18 months postdisaster. Finally, in a longitudinal study based on survivors of the 1998 earthquake in northern China, the rates of lifetime PTSD at 3 and 9 months postearthquake were 19% and 24%, respectively.

The long-term consequences of earthquakes were also reflected in a cross-sectional survey of survivors of the 1999 earthquake in Turkey. This study showed that 39% of the survivors living in shelters had PTSD and 19% had depression 20 months after the disaster. Similarly, other cross-sectional studies that involved assessments more than 3 years after an earthquake reported increased incidence of psychological distress and traumatic stress reactions in the survivors.

Factors Associated with Earthquake-Related Traumatic Stress

The lowest rates of psychiatric morbidity tend to be reported by survivors of earthquakes that caused relatively less devastation and fewer casualties, whereas survivors of more devastating earthquakes often show substantially higher rates of psychopathology. In general, existing studies suggest a strong positive association (dose-response relationship) between the degree of earthquake exposure and subsequent traumatic stress responses. Therefore, high exposure to earthquakes tends to relate to greater postearthquake psychological distress. High exposure to earthquakes involves exposure not only to more intense tremors but also to various other related traumatic stressors, such as damage to or collapse of the house, being trapped under rubble, physical injury, participation

in rescue work, witnessing grotesque scenes, loss of close ones, loss of property, and being relocated. On the other hand, low earthquake exposure involves experiencing relatively low-intensity tremors, with less exposure to additional stressors.

Recent studies suggested that the intensity of fear during an earthquake is a much stronger predictor of earthquake-related PTSD than other traumatic events, such as the extent of damage to house, being trapped under rubble, participation in rescue efforts, and being inside a building at the time of the earthquake. In addition, in most of these studies PTSD related to fear during the earthquake and other traumatic events, whereas depression related to loss (bereavement and material loss) and personal characteristics (e.g., history of psychiatric illness, marital status, and age). Other predictors of PTSD included female gender, personal or family history of psychiatric problems, and lower educational level.

Treatment of Earthquake Survivors

The interventions that have been used in the treatment of earthquake survivors include play or art therapy for children, family therapy, a didactic experiential group instruction program, debriefing, and brief crisis-oriented psychotherapy. Because most of these treatments were not tested by randomized controlled studies, their effectiveness has not yet been established.

In a randomized controlled study involving child survivors, 10 sessions of group play therapy reduced anxiety, but had no significant effect on depression and overall life adjustment. In another randomized controlled trial, six sessions of a combination of various interventions (trauma reconstruction and reprocessing, problem solving, relaxation techniques, and grief counseling) led to only a partial improvement in PTSD and had no effect on depression.

The usefulness of pharmacological agents in earthquake-related PTSD has not yet been adequately examined. In general, the PTSD literature contains relatively few randomized placebo-controlled trials of psychotropic drugs. The treatment effect sizes obtained in these studies were fairly small. Although there are some studies suggesting that SSRIs may be useful in reducing PTSD, most of them have not included a treatment-free follow-up period. Thus, we do not know whether the treatment gains were maintained in the long term in these studies. Furthermore, considering that relapse on discontinuation of medication is fairly common in anxiety disorders, the use of psychotropic medications in earthquake-related PTSD appears to be of dubious value.

Brief Modified Behavioral Interventions

The effectiveness of cognitive-behavioral treatment for PTSD is well established, and there is consensus among experts that it is the psychological treatment of choice for PTSD. Although cognitive-behavior therapy is considered a brief treatment (usually delivered in about 10 sessions), it is still too long in post-disaster circumstances in which thousands of people may require help. Furthermore, other factors, such as postdisaster hardships and demographic mobility, often interfere with the survivors' ability to attend treatment sessions regularly. Such circumstances require much briefer interventions, preferably involving no more than one or two sessions.

A series of studies in Turkey examined whether cognitive-behavioral treatment could be shortened without compromising its effectiveness. In an open clinical trial, 231 survivors with chronic PTSD symptoms received a modified version of behavioral treatment and were assessed weekly to determine the minimum number of sessions required for significant clinical improvement. The treatment involved no systematic cognitive restructuring and focused only on reducing behavioral avoidance by giving instructions for systematic self-exposure to feared and avoided situations. The rationale of the treatment was not based on habituation that emphasizes reduction in distress during exposure (e.g., "Stay in the situation until your anxiety subsides") but on enhancement of sense of control over fear and distressing trauma reminders (e.g., "Stay in the situation until you gain control over your anxiety/distress").

The survivors were given a mean of 4.3 sessions and a survival analysis showed that 76% of them improved after one session and 88% after two sessions. The mean number of sessions required for significant improvement was 1.7. The results revealed a patholytic treatment effect, with significant improvement in PTSD, depression, and overall adjustment. Improvement was maintained at the 3- and 9-month follow-ups; of the 75 survivors who had a 9-month follow-up assessment, only one showed relapse.

This study suggested that modified behavioral treatment may be effectively delivered in one session. To examine this hypothesis, a randomized waitlist controlled trial was conducted, involving 59 earthquake survivors who were given only one session of modified behavioral treatment. Blind assessment at week 6 showed significant treatment effects on all study measures, including PTSD, depression, fear of earthquakes, and overall adjustment. The overall improvement rate was 49% at week 6, 80% at week 12, 85% at week 24, and 83% at 1–2 years posttreatment.

In another clinical study, 10 survivors with chronic PTSD symptoms received a single session of exposure treatment in an earthquake simulator (a small furnished house resting on a shake table that simulates tremors on nine intensity levels). A control switch inside the simulator allowed survivors to stop and start the tremors and increase their intensity whenever they felt ready for it. The treatment was aimed at enhancing the survivors' sense of control over simulated tremors and anxiety-evoking memories of trauma. Assessments at pre- and postsession and at 2, 4, 8, and 12 weeks posttreatment revealed significant improvement in all measures of psychopathology. Eight patients were markedly and two slightly improved at follow-up. The effectiveness of this treatment was further ascertained in a randomized controlled treatment that involved 30 subjects.

These studies also provided some evidence that fear reduction through modified behavioral treatment may have protective effects against the traumatic effects of future earthquakes. Many of the survivors were treated during the first year after the disaster when the aftershocks were continuing. Despite the additional traumatic effects of these aftershocks, relapse after recovery was rare, suggesting that the treatment had a protective effect. The survivors often reported that they no longer panicked during real earthquakes as they used to in similar occasions before treatment. Behavioral treatment involving exposure to simulated tremors in an earthquake simulator was particularly effective in reducing fear and enhancing a sense of control over future earthquakes, suggesting that this intervention might have a potential use in increasing psychological preparedness for earthquakes.

Dissemination of treatment to large numbers of survivors after natural disasters is a critical issue, particularly in developing countries with limited mental health-care resources. A pilot study in Turkey examined the usefulness of a highly structured self-help manual in delivering modified behavioral treatment to survivors. When the manual was delivered to 89 survivors with PTSD in the community, one in four survivors read the manual, complied with the treatment instructions, and reported significant improvement in their problems.

These studies show that brief and modified versions of behavioral treatment are both practical and effective in postearthquake settings. These interventions lead to significant and sustainable improvement while reducing therapist time to a minimum. In addition, the dissemination of the treatment through self-help manuals to large numbers of survivors may be a cost-effective way of dealing with the widespread posttraumatic stress responses in the community.

Further research is needed to examine whether the development of PTSD can be prevented by brief modified behavioral treatment delivered in the early aftermath of an earthquake. In addition, randomized controlled studies are needed to confirm the effectiveness of various methods of treatment dissemination (e.g., through manuals, computers, videocassettes, and television).

Prevention

Given the inevitability of earthquakes, preparedness for future earthquakes is of utmost importance. Undoubtedly, the first preventive measure against the mental health hazard posed by earthquakes involves measures designed to reduce the extent of devastation and casualties caused by earthquakes, such as stricter building regulations, effective emergency response policies, and training of the public in self-protection. Accordingly, much of the effort has concentrated on this aspect of earthquake preparedness. What is less clear, however, is how people can be prepared psychologically against earthquakes. Recent work in Turkey provided some insight into effective methods of enhancing psychological preparedness in people at risk of earthquakes. Considering that fear plays an important role in the development of PTSD in earthquake survivors, interventions designed to enhance a sense of control over fear might be expected to increase psychological resilience against the traumatic effects of earthquakes. Evidence suggests that this could be effectively achieved by behavioral interventions, particularly by those involving the use of an earthquake simulator. Further research in this area appears to be worthwhile.

Clinical Overview of Eating Disorders

Anorexia Nervosa

Bulimia Nervosa

Etiological Influences in Eating Disorders

Glossary

<i>Amenorrhea</i>	A symptom of anorexia nervosa in adolescent and adult women, characterized by the failure of menstrual cycles to occur during three or more consecutive expected cycle intervals.
<i>Binge-eating episode</i>	consumption of an abnormally large amount of food in a discrete episode, during which eating feels out of control.
<i>Hypothalamus</i>	A region in the lower part of the brain involved in the regulation of eating behavior, as well as the modulation of other metabolic and hormonal systems.
<i>Neuro-transmitter</i>	A naturally occurring neurochemical which participates in the selective transmission of signals in neuronal pathways modulating behavior and physiological functions.
<i>Purging behaviors</i>	In patients with eating disorders, symptoms intended to control body weight by eliminating ingested foods and liquids; examples include self-induced vomiting and misuse of laxatives.
<i>Restricting behavior</i>	In patients with eating disorders, a pattern of strict limitation of food intake in order to control body weight.
<i>Serotonin</i>	A naturally occurring neurochemical which acts as a neurotransmitter in the central nervous system, including pathways modulating meal size and mood.

Clinical Overview of Eating Disorders

In recent years there has been increasing awareness of the prevalence of anorexia nervosa and bulimia nervosa, and the personal and social costs associated with these disorders. This awareness has been reflected in attention to these problems in the lay press and in professional publications. Clinical investigations have

yielded new insights into the prevalence and symptom patterns of anorexia nervosa and bulimia nervosa. Although the etiology of these disorders is unknown, potential psychosocial and biological risk factors have been identified, and new treatment approaches have been developed. This article provides an overview of clinical characteristics of these disorders, and highlights several directions of recent research advances. Consultation with a medical and/or mental health professional is important for an individual seeking specific guidance regarding clinical evaluation and treatment.

Anorexia Nervosa

Clinical Characteristics

Anorexia nervosa is widely recognized as a syndrome of weight loss which is associated with fears of unwanted weight gain, and is not a consequence of other medical illness. Symptoms of anorexia nervosa were first described in the medical literature more than 100 years ago. Specific diagnostic features of the syndrome are outlined in the *Diagnostic and Statistical Manual of Mental Disorders, 4th edn. (DSM-IV)*. The most prominent features of anorexia nervosa include weight loss below 85% of an individual's expected body weight, associated with an intense fear of excessive weight gain and abnormal perception of body-weight status. An additional characteristic of the disorder in adolescent and adult females is a period of amenorrhea, usually thought to be a consequence of low body weight. Approximately half of individuals with anorexia nervosa exhibit binge-eating or purging behaviors associated with efforts to maintain a low weight, while others engage predominantly in food restriction. Based on DSM-IV diagnostic categories, these individuals are grouped into binge eating-purging type and restricting type, respectively.

Anorexia nervosa is associated with a range of medical problems which are thought to be primarily related to malnutrition and weight loss. Among the more common problems are anemia, abnormalities in blood pressure and heart rhythm, and alterations in blood electrolyte levels. Activity in the hypothalamic-pituitary-adrenal axis is often increased, with malnutrition-related elevations in blood levels of the stress-related hormone, cortisol. Consistent with physiological adaptations to conserve energy, functional activity in the hypothalamic-pituitary-thyroid axis and the sympathetic nervous system are frequently decreased. Reduction in bone mineral density with increased risk of bone fractures is often a

long-term consequence of severe malnutrition in anorexia nervosa.

Naturalistic follow-up studies indicate that at 5–10 years after initial assessment, about 40–60% of patients achieve stable weight recovery, while 10–20% of patients continue to have symptoms of the disorder. In general, it is difficult to predict an individual's long-term outcome based on initial symptomatology. The estimated mortality associated with anorexia nervosa is approximately 6% during the first 10 years after initial assessment, with variability in findings most likely reflecting the severity of initial symptomatology.

Epidemiology and Psychiatric Comorbidity

The average age of onset of anorexia nervosa is approximately 18 years, although a significant number of patients experience an early age of onset (i.e., at 8–14 years). Anorexia nervosa is approximately 10 times more prevalent in females than in males. Among young women, the group at highest risk for the disorder, the prevalence of anorexia nervosa has been estimated as approximately 0.5%. Although epidemiological data are limited, it is known that anorexia nervosa can occur in individuals of various ethnic backgrounds and socioeconomic classes.

Individuals with anorexia nervosa often have a history of additional psychiatric symptoms, particularly depression and anxiety disorders, including obsessive-compulsive disorder. It is of note that marked weight loss in healthy volunteers has been shown to result in depressive symptoms and preoccupation with food. Thus, for some anorexic patients, depressive symptoms may improve with nutritional stabilization and weight restoration.

Overview of Treatment Approaches

For patients with acute weight loss with life-threatening medical and psychiatric symptoms, hospitalization may be necessary. Following medical stabilization, inpatient treatment often includes a behaviorally oriented weight-restoration program with a gradual increase in caloric intake. Individual, group, and family psychotherapy (especially for younger patients) are commonly employed. For less severely ill patients, day hospital treatment or outpatient therapy is usually recommended. Available medication treatments appear to be of only limited benefit in achieving weight restoration, although they may be particularly helpful for symptoms of depression and anxiety. Following weight restoration, a significant number of individuals experience a relapse to low-weight episodes. Again, available medication

treatments appear to have only limited benefit in preventing relapse.

Bulimia Nervosa

Clinical Characteristics

The hallmark symptom of bulimia nervosa is the binge-eating episode. In the *DSM-IV*, a binge-eating episode is characterized as consumption of an abnormally large amount of food in a discrete episode, during which eating feels out of control. Although binge eating had previously been recognized in patients with anorexia nervosa, during the 1970s clinicians noted a syndrome of binge eating that occurred in individuals in a normal weight range. Current diagnostic criteria for bulimia nervosa specify that binge-eating episodes, along with compensatory behaviors designed to avoid weight gain, occur on average at least twice a week over a period of at least 3 months. Additionally, body shape and weight play an excessively large role in influencing the individual's sense of self-worth. For some patients, compensatory behaviors include purging activities such as self-induced vomiting or laxative misuse, while for others, fasting or excessive exercise are the main weight control strategies.

Although nutritional abnormalities may result in medical symptoms in patients with bulimia nervosa, these are usually less marked than in anorexia nervosa. It has been recognized, however, that purging behaviors can contribute to significant alterations in blood levels of potassium and other electrolytes, potentially leading to serious heart arrhythmias. A range of other serious medical complications have also been reported. Abnormalities in neuroendocrine hormone levels are not infrequent in bulimia nervosa, being associated with such symptoms as abnormal menstrual cycle patterns in up to 50% of patients.

Follow-up studies ranging up to 10 years following initial assessment indicate that approximately 50–60% of patients with bulimia nervosa will have recovered from the disorder. Approximately one-third of individuals will have significant persisting symptoms, and 10–15% will still meet criteria for the disorder. It is not uncommon for individuals to have one or more relapses, particularly during the first 6 months following their initial recovery from symptoms.

Recently there have been a number of clinical studies of a syndrome provisionally identified as binge-eating disorder. Binge-eating disorder is similar to bulimia nervosa in that affected individuals have recurrent episodes of binge eating. In contrast to bulimia nervosa, individuals with binge-eating disorder do not

engage in recurrent inappropriate compensatory behaviors designed to counteract the caloric intake associated with binge eating. Thus, binge-eating disorder is commonly associated with obesity. Further research is needed to clarify the role of psychosocial environment, stressful life situations, and biological characteristics as risk factors for binge-eating disorder.

Epidemiology and Psychiatric Comorbidity

Similar to anorexia nervosa, the average age of onset of bulimia nervosa is approximately 18 years, with a female to male ratio of approximately 10:1. Based on current diagnostic criteria, bulimia nervosa is estimated to occur in 1–3% of young women.

Approximately 50% of patients with bulimia nervosa have an episode of major depression, either concurrent with, or at a time separate from, the eating disorder. Other relatively common comorbid psychiatric symptoms in patients with bulimia nervosa include substance-use disorders and anxiety disorders.

Overview of Treatment Approaches

Patients with bulimia nervosa are most often treated in an outpatient setting, although life-threatening psychiatric symptoms (such as active suicidal ideation) or medical complications may lead to hospitalization. Clinical psychotherapy trials have focused primarily on structured short-term therapies (e.g., cognitive behavioral treatment or interpersonal treatment) lasting 4–5 months. These treatments generally achieve greater than a 50% decrease in binge frequency, with a substantial number of patients achieving abstinence from binge episodes. Additionally, placebo-controlled trials have shown that a range of antidepressant medications can significantly decrease frequency of bulimic episodes for many individuals. Current treatment research includes comparative trials of stepped-care approaches such as an initial trial of self-help guided by a health-care provider, and studies of sequential treatments for individuals who do not show evidence of improvement as psychotherapy proceeds.

Etiological Influences in Eating Disorders

Psychosocial and Biological Risk Factors

Although clinical investigations have identified important leads, specific etiological factors responsible for anorexia nervosa and bulimia nervosa remain unknown. Cultural factors leading to increased emphasis on slender appearance are generally thought to

contribute to an increased prevalence of eating disorders. Stresses associated with school transitions and occupational demands have been suggested as possible contributors to the increased risk for the eating disorders among adolescents and young adults.

Clinical investigations have demonstrated increased ratings of perfectionistic character traits and depressive symptoms in anorexia nervosa. Research on risk factors suggests that perfectionism and low self-evaluation may be associated with the later development of anorexia nervosa.

The onset of bulimia nervosa is often preceded by extended periods of recurrent dieting occurring in the context of other psychosocial stressors. Other behavioral characteristics that have been identified in patients with bulimia nervosa include impulsivity and mood lability, and it is possible that these traits may contribute to the onset or perpetuation of symptoms in this disorder. Several psychological models of binge-eating behavior have been proposed. In one model, for example, an individual attempting to follow a reduced calorie diet may experience an abstinence violation effect following ingestion of modest amounts of snack foods, leading to a transient inclination to abandon dietary restraint altogether. Factors that may lead to dieting, such as parental or childhood obesity, have been identified as potential risk factors for the development of this disorder.

Psychobiological Models

Family studies have shown that there is an increased rate of eating disorders in first-degree relatives of individuals with anorexia nervosa and bulimia nervosa. Similarly, twin studies have shown a higher concordance for the eating disorders in monozygotic twins in comparison to dizygotic twins. These studies suggest that heritable biological characteristics contribute to the onset of the eating disorders, although the potential role of familial environmental factors must also be considered.

Biological factors are likely to contribute to one or more dimensions of symptomatology in eating disorders. Neurotransmitters, neuropeptides, and related neuromodulators have been shown to act in the central nervous system, particularly in the hypothalamus, to modulate hunger and satiety. Recent research has shown that peptides released from the gastrointestinal tract help to regulate eating behavior. For example, preclinical studies have shown that naturally occurring neurochemicals such as ghrelin can substantially increase food intake and body weight, while other neuropeptides such as cholecystokinin can decrease food intake. Thus, binge-eating episodes

characteristic of bulimia nervosa may reflect the interaction of stressful psychosocial events with abnormalities in the release of meal-regulating peptides such as ghrelin and cholecystokinin. There has also been recent interest in the metabolic signaling protein, leptin, which is produced in adipose tissue and released into the circulation. Dieting and weight loss is associated with a decrease in leptin levels. It has been hypothesized that a marked reduction in blood leptin levels may play a role in menstrual cycle abnormalities commonly associated with anorexia nervosa.

The neurotransmitter serotonin has been the focus of considerable research in patients with anorexia nervosa and bulimia nervosa. Laboratory studies have shown that patients with eating disorders often experience abnormal patterns of hunger and satiety over the course of a meal. Serotonin plays an important role in postingestive satiety, and appears to be important in regulation of mood and anxiety-related symptoms. Preliminary findings suggest that impaired function in central nervous system serotonergic pathways may contribute to binge eating and mood instability in bulimia nervosa. Dieting behaviors may tax the adaptive capacities of serotonergic pathways. Therapeutic effects of antidepressant medications in bulimia nervosa are thought to be related to their capacity to restore more normal signaling patterns in serotonergic pathways.

Recent studies have also explored whether abnormalities in metabolic signals related to energy metabolism contribute to symptoms in the eating disorders. Several studies have suggested that patients with bulimia nervosa may have a lower rate of energy utilization (measured as resting metabolic rate) than healthy individuals. Thus, a biological predisposition toward greater than average weight gain could lead to preoccupation with body weight and food intake in bulimia nervosa.

Maternal and Perinatal Outcome

History

Epidemiology

Pathophysiology

Prediction of Pre-Eclampsia

Prevention of Pre-Eclampsia

Management of Pre-Eclampsia

Glossary

<i>Eclampsia</i>	Occurrence of seizures in a woman with pre-eclampsia that cannot be attributed to other causes.
<i>Invasive trophoblast</i>	The inner trophoblast lineage which differentiates into tumorlike cells that invade the lining of the pregnant uterus and the maternal uterine spiral arteries.
<i>Oxidative stress</i>	A disequilibrium between antioxidant defenses and production of reactive oxygen species in favor of the latter.
<i>Pre-eclampsia</i>	A pregnancy-specific syndrome that occurs after mid-gestation, defined by the <i>de novo</i> appearance of hypertension (systolic blood pressure of ≥ 140 mmHg or diastolic blood pressure of ≥ 90 mmHg), accompanied by new-onset proteinuria (defined as ≥ 300 mg per 24 h).
<i>Pregnancy-induced hypertension</i>	<i>De novo</i> hypertension arising after mid-gestation distinguished from pre-eclampsia by the absence of proteinuria.

Pre-eclampsia is a multisystem disorder of unknown etiology, which is unique to pregnancy. Women with pre-eclampsia usually develop hypertension and proteinuria, but the condition is also associated with abnormalities of the blood coagulation system, disturbed liver function, renal failure, and cerebral ischemia. The incidence of pre-eclampsia is 2–10%, depending on the population studied and definitions of pre-eclampsia. Eclampsia, the occurrence of one or more convulsions superimposed on the syndrome of pre-eclampsia, occurs less frequently. In the Western world, the reported incidence of eclampsia ranges from one pregnancy in 2000 to one in 3448.

Maternal and Perinatal Outcome

Pre-eclampsia is a major obstetric problem leading to substantial maternal and perinatal morbidity and mortality worldwide, especially in developing countries. In general, maternal and perinatal outcomes are usually favorable in women with mild pre-eclampsia developing beyond 36 weeks of gestation. By contrast, maternal and perinatal morbidities and mortalities are increased in women who develop the disorder before 33 weeks of gestation, in those with pre-existing medical disorders, and in those from developing countries. Eclampsia compared to pre-eclampsia carries a much higher risk of death and serious morbidity for the woman and her baby. In the UK, for example, one in 50 of the women who have eclampsia die.

History

Eclampsia was defined by Celsus in 100 AD as seizures during pregnancy that abated with delivery. For the ensuing 1700 years, eclampsia was considered a pregnancy-specific seizure disorder. It was not until the mid-1800s that the similarity of the edematous eclamptic women and the dropsic patients with Bright's disease (acute glomerulonephritis) stimulated clinicians to determine whether women with eclampsia, like individuals with Bright's disease, had protein in their urine. Protein was indeed present and 50 years later an association of increased blood pressure and eclampsia was recognized. It was soon evident that hypertension and proteinuria during pregnancy, even without seizures, identified a woman with the potential for a rapidly progressive life-threatening disorder and a fetus at increased risk of stillbirth.

Epidemiology

Several risk factors have been identified with increased risk of pre-eclampsia. These factors include a previous history of pre-eclampsia, nulliparity, maternal age over 40 years, family history of pre-eclampsia, limited sperm exposure, multiple pregnancies, obesity, and chronic medical conditions such as chronic hypertension, renal disease, insulin-dependent diabetes (IDDM), autoimmune disease, and antiphospholipid syndrome. Paradoxically, smoking during pregnancy has been associated with a reduced risk of pre-eclampsia.

Studies conducted to determine the relation between job strain and hypertensive complications during pregnancy showed that work-related psychosocial stress increased the risk of pre-eclampsia. Indeed stressful job characteristics did show associations with pregnancy-induced hypertension. In particular, gestational hypertension was associated with low decision latitude and low job complexity among women in lower-status jobs and with job pressures/low control among women in higher-status jobs.

Pathophysiology

Reduced Placental Perfusion, Oxidative Stress, and Pre-Eclampsia

Although the causes of pre-eclampsia remain still unknown, it is generally agreed that pre-eclampsia arises from the placenta and/or the maternal response to placentation. The clinical syndrome is characterized by secondary systemic circulatory disturbances that can be ascribed to generalized maternal endothelial dysfunction. Pre-eclampsia is appropriately divided into two stages: alterations in placental perfusion and the maternal syndrome. In placental pre-eclampsia, the problem arises from a placenta that is under hypoxic conditions and oxidative stress. Once defective placentation is established, reduced perfusion appears to interact with maternal factors to result in the maternal syndrome. These factors are posited to be genetic, behavioral, or environmental.

The placenta seems to be the key component of pregnancy that leads to pre-eclampsia. During the first half of normal human pregnancy, uteroplacental arteries undergo a series of pregnancy-specific changes that include the replacement of endothelial and media smooth muscle cells by invasive trophoblast cells, loss of elasticity, dilatation to incontractile tubes, and loss of vasomotor control, which allows a substantial increase in blood supply to the growing fetus. In pre-eclampsia, spiral arteries undergo superficial or no remodeling and this results in reduced placental perfusion.

A principal question is how reduced perfusion of the placenta can result in the maternal syndrome. Oxidative stress has been proposed as the link between the two phases of pre-eclampsia. The oxidative stress hypothesis proposes that hypoxia at the fetal-maternal interface results in the generation of free radicals that may lead to oxidative stress by the following potential mechanism: hypoxia stimulates xanthine oxidase, an important source of superoxide generation. As a result, the placenta releases what can be described as trophoblastic debris into the maternal circulation. This comprises syncytiotrophoblast

membrane microparticles, cytokeratin fragments, soluble ribonucleic acid (RNA) and deoxyribonucleic acid (DNA) of fetal origin and even cytotrophoblast cells. Syncytiotrophoblast microvesicles, normally present in the circulation in pregnancy, are increased in pre-eclampsia and have been directly linked to activation of maternal neutrophils, which in turn may contribute to endothelial cell activation.

In pre-eclampsia, the hypoxia/reperfusion injury leads also to increased expression of nicotinamide adenine dinucleotide phosphate (NAD(P)H) oxidase and hence increased superoxide generation in placental tissue. Potential additional stimuli to activation of NAD(P)H oxidase in pre-eclampsia include raised feto-placental vascular shear stress, elevation of maternal plasma cytokine concentrations, and enhanced angiotensin II sensitivity.

Abundant evidence of oxidative stress in placenta, tissues, and blood of women with pre-eclampsia support the oxidative stress hypothesis. These oxidative damage biomarkers include higher placental levels of markers for lipid peroxidation such as the F_2 -isoprostanes and malondialdehyde and for non-lipid markers, including increased nitrotyrosine residues in fetal blood vessels. Supportive of a role for oxidative stress in the maternal circulation is the maternal plasma elevations of lipid peroxidation products, including malondialdehyde (MDA), conjugated dienes, F_2 -isoprostanes (usually 8-epi-prostaglandin $F_{2\alpha}$), and antibodies against oxidatively modified low-density lipoprotein (LDL). Besides the elevation of lipid peroxidation markers, another indication of the presence of oxidative stress is the decreased antioxidant capacity in the maternal circulation. Indeed, women with pre-eclampsia have lower plasma concentrations of glutathione, a major intracellular water-soluble antioxidant.

Stress and Pre-Eclampsia

The hypothalamic-pituitary-adrenal (HPA) axis, along with the arousal and sympathetic nervous systems (SNS), constitute the stress system. Activation of the stress system leads to behavioral and peripheral changes that improve the ability of the organism to adjust homeostasis and increase its chances for survival. The principal regulators of the HPA axis are corticotropin-releasing hormone (CRH) and arginine-vasopressin (AVP), both produced by parvocellular neurons of the paraventricular nucleus of the hypothalamus and secreted into the hypophyseal portal system. CRH and AVP synergistically stimulate pituitary adrenocorticotrophic hormone (ACTH) secretion and subsequently cortisol secretion by the adrenal cortex.

CRH and its receptors have been identified in several female reproductive organs, including the ovaries, endometrial glands, decidualized endometrial stroma, and placenta. Placental CRH is produced by the syncytiotrophoblast, placental decidua, and fetal membranes. In pregnant women, the placenta is the main source of circulating CRH, as supported by undetectable levels of circulating CRH levels in non-pregnant woman. The biologic activity of placental CRH is attenuated by the presence of a circulating CRH-binding protein (CRH-BP), a 37-kD protein of 322 amino acids that binds circulating CRH and modulates CRH actions on pregnant target tissues during pregnancy. To optimize placental perfusion during pregnancy, the umbilical-placental vessels are normally maintained in a state of physiological dilatation by the action of locally produced vasodilators. CRH is a potent dilator of placental resistance vessels, acting via production of nitric oxide (NO). Maternal plasma CRH concentrations are significantly elevated in complicated pregnancies.

The mean umbilical cord plasma CRH in pre-eclamptic pregnancies is significantly higher than that from normotensive pregnancies. This is also reflected by maternal plasma CRH levels that are significantly higher in hypertensive women than those with uncomplicated pregnancies. Moreover, in women with pregnancy-induced hypertension, CRH-BP levels are significantly lower in patients who progressed to pre-eclampsia. CRH-BP may be involved in the paracrine regulation of vasodilator CRH effects in human placenta. In this regard, the reduced secretion of CRH-BP may enhance and amplify the effects of CRH by increasing its biologically active free fraction. Taken together these findings suggest that in pre-eclampsia or eclampsia the placenta takes part in a stress syndrome by releasing CRH, which may help improve uterine perfusion thereby protecting the fetus from anoxia and starvation. Indicative of a stress-responsive compensatory mechanism in the human placenta is the fact that the concentration of CRH in the fetal circulation is significantly increased in pregnancies complicated by abnormal umbilical artery flow-velocity waveforms.

In pregnancies complicated by pre-eclampsia, the plasma levels of CRH are elevated, together with a concomitant reduction in CRH receptor type 1 α (CRHR1 α) and type 2 (CRHR2) expression. The dampening of CRH-induced vasodilatation in pre-eclamptic placentas could be attributable to loss of CRHRs. Although in normal placenta there is a balance between the vasodilatory action of CRH and the opposing actions of vasopressor agents, such as angiotensin II, in pre-eclampsia upregulation of

angiotensin II receptors (AT₁R) and formation of heterodimers with bradykinin B₂ receptors (B₂R) alter this balance and further potentiate the vasoconstriction caused by angiotensin II. Enhanced angiotensin II activity induces secretion of placental CRH, which, in turn, can downregulate its own receptors leading to abnormal vascular resistance and the clinical sequelae of pre-eclampsia.

One of the signaling pathways mediating CRH actions during pregnancy appears to be the nitric oxide (NO)/cyclic guanosine monophosphate (cGMP) pathway. This signaling pathway appears to play an important role in vascular adaptation and placental physiology by mediating the vasodilatory effects of agonists in resistance vessels, which helps in the maintenance of low vascular resistance in the fetoplacental circulation. In pre-eclampsia the placental CRH-R down-regulation and the associated inability of CRH and CRH-related peptides to stimulate the NO/cGMP pathway might result in the disturbance of the balance controlling vascular tone towards vasoconstriction. In addition to CRH, other hormones with vasodilatory actions involved in the stress response, such as ACTH and cortisol, are increased in the fetuses of pre-eclamptic pregnancies, underscoring the role of the placental stress syndrome in the disease.

The role of CRH in the regulation of pituitary adrenocorticotropin secretion and the stress response is well established. In recent years, association of abnormally high placental expression of CRH with pregnancy complications, such as pre-eclampsia and intrauterine growth restriction (IUGR), suggest that CRH output from the placenta is specifically increased in response to fetal stress. Placental CRH activates a number of potentially useful adaptive responses for the stressed fetus. These include maximization of placental blood flow, acceleration of fetal organ development, and the early initiation of labor when fetal survival is threatened.

Besides the activation of the HPA axis, stress is associated with the activation of the SNS and hence with elevated serum levels of catecholamines. Enhanced release of catecholamines is postulated to aggravate the already existing vasoconstriction in pre-eclampsia, whereas, in normal pregnancy, loss of vasomotor control keeps vessels relatively insensitive to vasoactive substances.

Prediction of Pre-Eclampsia

A variety of biochemical markers, based primarily on the above rationale implicated in the pathophysiology of pre-eclampsia have been proposed to predict the development of pre-eclampsia later in pregnancy.

Only markers related to placental stress syndrome are discussed in this section.

Although there is an inverse relation between reduced plasma CRH-BP levels and increased CRH levels in the maternal circulation of patients with pregnancy-induced hypertension, the measurement of these polypeptides in maternal plasma does not predict the development of pre-eclampsia because these hormonal changes do not occur before the onset of disease. Measurements, however, of CRH and CRH-BP in pregnant women who are at-risk for pre-eclampsia may add significant prognostic information for predicting pre-eclampsia, as the probability of the disease was shown to be remarkably higher among women with positive than in women with negative double-hormone tests.

In women with pre-eclampsia, the combination of elevated lipid peroxidation markers and decreased antioxidant capacity has raised the possibility that markers of oxidative stress might prove useful in the prediction of the disease. However, data for the reliability of these markers in suggesting pre-eclampsia have been inconsistent because of the difficulties and variability in the methods of measurement. As pre-eclampsia is of multifactorial origin, the determination of a single biochemical marker is unlikely to provide adequate predictive power.

At present, the best predictive test involves assessment of the velocity of uterine artery blood flow in the second trimester, however this test is still not recommended for routine screening of pregnant women for pre-eclampsia.

Prevention of Pre-Eclampsia

During the past decade, several trials reported the use of various methods to reduce the rate or severity of pre-eclampsia. Although prevention trials have been disappointing to date, the evidence for oxidative stress in pre-eclamptic women indicates that there may be a role for antioxidant vitamins C and E for prophylaxis. Large multicenter trials are now underway and will determine whether antioxidant prophylaxis may be used routinely in the prevention of pre-eclampsia.

Management of Pre-Eclampsia

The most important factor in the management of pre-eclampsia is adequate and proper prenatal care. After diagnosis, subsequent treatment will depend on the results of initial maternal and fetal assessment. Mother always takes the first priority in the management of pre-eclampsia and thus delivery remains the

ultimate treatment. When possible, vaginal delivery is preferable to avoid the added physiologic stressors of a cesarean section. Since delivery is not always the best choice for a very premature fetus, the decision between delivery and expectant management depends on the severity of maternal condition, the fetal status, and fetal gestational age at the time of assessment.

Policy Implications and Conclusions

Glossary

<i>Discount rate of pain</i>	A measurement of the difference between fear of pain experienced now and of that experienced in the future.
<i>Expected value of pain</i>	The product of multiplying the likelihood of experiencing a painful event by the amount pain it would inflict.
<i>Reservation wage</i>	The wage at which a worker with chronic illness will apply for disability benefits rather than compete for a job.
<i>Social support</i>	Tangible and intangible help from family, friends, and social networks to cope with stressors.

Introduction: The Economy as a Population Stressor

We intuitively separate the stressors associated with physiological and behavioral disorders into several groups. These groups include undesirable as well as intuitively desirable job and financial events. As might be expected, the incidence of undesirable job and financial stressors increases during periods of economic contraction. The experience of undesirable job and financial events by a principal wage earner also increases the risk of disorder for his or her spouse and family. Undesirable job and financial experiences,

moreover, increase the likelihood of subsequent stressful nonjob, nonfinancial experiences for the wage earner and his or her family. The contraction of a regional economy can, in other words, increase the experience of undesirable job and financial events that, in turn, increase the risk of experiencing yet other undesirable experiences not intuitively related to the economy. These undesirable events raise the risk of disorder not only for those who experience them, but also for spouses and other members of the family.

Researchers have focused on job loss more than any other economic stressor. While disagreement remains over the virulence of job loss as a pathogen, there is agreement that forced job loss increases the risk of depressed mood, alcohol abuse, and antisocial behavior. More controversy arises from claims of a connection with somatic illness, but job loss reportedly increases the risk of stress-related illnesses, including those associated with compromised endocrine and immune responses.

Persons exposed to undesirable job and financial events early in life may exhibit elevated risk of succumbing to future stressors, whether those are economic in nature or not. Research on those who experienced the Great Depression of the 1930s, for example, suggests that economic stressors can affect behavior well into the future.

Classic and recent theoretical literature concerned with the economy as a source of stressors posits that economies expanding more quickly than the rate to which a population has habituated should be pathogenic. This work argues that movements away from the expected value of macroeconomic performance, regardless of direction, should increase the incidence of stress-related illness. Individual-level research has not found desirable job and financial events to be as virulent or as contagious as undesirable events, but reports of ecological associations between rapid economic growth and the incidence of trauma and alcohol-related pathology appear in the literature. Fear of job loss, moreover, appears to reduce risk-taking behavior such as alcohol use and antisocial

behavior. The pure income effects of changing economies could also affect the incidence of pathology in that more income makes risk taking more likely, while less income should suppress risk taking that requires outlay.

The known and suspected health effects of economic expansion raise an important issue for those who would estimate the health and behavioral cost of economic perturbations. Such estimates will be of the net effect of change and therefore require more empirical research than we now have into pathology induced by economic growth.

The Economy's Effect on Hazard Avoidance

The classic and contemporary stress literature connects environmental stressors to illness through the presumed effects of stressors on the endocrine and immune systems. Stressors, however, may affect health through other avenues, such as the effects of stressors on hazard avoidance.

We have a fixed capacity to assess, manage, or reduce hazards in our physical and social environments. We budget this capacity in that not all hazards receive equal attention. Candidates for less attention include hazards with the least potential for pain. Potential for pain is the product of the expected value of pain and our discount rate. The expected value, in turn, is the product of the likelihood of succumbing to the hazard and the pain that doing so would inflict. The discount rate gauges the difference in fear of pain experienced now compared to that experienced in the future. We most likely neglect hazards that promise relatively little pain, have a low probability of occurring, and occur farthest in the future.

If a contracting economy confronts us with new and immediate hazards, those already low on our list for attention may fall off the list all together. Screening for the early signs of treatable disease or compliance with treatment regimens, for example, may decline among persons attending to hazards posed by lost income.

Attending to new hazards at the expense of old might not change the incidence of illness in a population if hazards came into and left our lives for reasons peculiar to each of us. Some of us would be experiencing new hazards while others were losing old ones, leaving the net effect in the population at or near zero. Incidence would, however, vary over time if the environments we share became more or less hazardous. We all share the constantly shifting economic environment.

The early detection of breast cancer provides an example of how the economic environment may affect the incidence of serious illness by causing shifts in attention across hazards. Ninety-three percent of

women discovered with local breast cancer survive 5 or more years, but only 18% of those discovered with remote tumors do so. It appears that living in a contracting economy reduces the likelihood that women will discover tumors in the local stage. Women apparently seek less screening when coping with the sequelae of economic contraction. They do not, in other words, have sufficient capacity to attend to both the new hazards inflicted upon them by economic contraction and the old hazards farther down the list of priorities.

As noted earlier, changing economies have income effects such that expansion enables individuals to consume more while contraction tends to reduce consumption. Some individuals may use added income to pursue activities that expose them to more hazards than would otherwise be the case. Indeed, ecological associations between rapid economic growth and the incidence of trauma may reflect the risk taking enabled by economic expansion.

The Economy's Effect on Coping Assets

The stress literature posits, without great controversy, that coping assets mediate an individual's response to stressors. These assets can be genetic or acquired through interactions with the environment. The latter can be further separated into those that are unintentionally acquired (e.g., immunities induced by naturally occurring exposures to infectious pathogens) and those sought out (e.g., vaccines). Intentionally acquired coping assets include those purchased with money and those acquired through social arrangements analogous to mutual aid societies or insurance pools. While some have speculated regarding the effect of economic forces on unintentionally acquired, and even genetically endowed, coping assets, the empirical work focuses on those purchased with money or obtained through social arrangements.

Coping assets purchased with money include goods and services explicitly marketed as means to bolster one's capacity to deal with new or chronic stressors. These assets include professional medical care, leisure activities, organized exercise activity, and dietary supplements. Other goods and services can also help persons cope with stressors. Advertisers may not often cast nutritious food, decent housing, and entertainment, for example, as stress buffers, but much of the value of these products in the market may well arise from this function. The performance of the economy obviously affects our ability to acquire these resources because it affects how much money we have to spend. Money, in effect, is a generalized coping asset.

The performance of an economy also affects the availability of coping assets acquired outside the market. The literature pays much attention to social

support and social capital as mediators of the stress response. These terms refer to all sorts of tangible and intangible resources obtained by stressed persons from their families, social networks, and public and private institutions.

The insurance pool metaphor conveys the effect of the economy on social support and capital. Social networks can be thought of as informal insurance pools to which participants not coping with stressors contribute surplus coping assets, and from which participants coping with stressors draw assets. As with all insurance pools, the arrangement works only if demands do not exceed the pooled resources. Participants in such pools often underestimate how many resources a pool needs because we intuitively make the actuarial assumption that the incidence of stressors remains relatively constant although those who suffer them may vary. If, however, an ambient shock stresses many persons in the pool, the demand for resources can be unexpectedly high and deplete the pool. A contracting economy acts as an ambient stressor that causes an unexpectedly large number of individuals and their families to suffer stressful losses and to resort to social networks for coping resources. Other members of the network who fear such a loss withdraw contributions to the pool, believing they themselves will need them. The incidence of stress-related illness therefore rises because social support cannot be gotten from an actuarially insufficient pool. Persons dealing with chronic stressors or stressful events unrelated to the economy also exhibit elevated incidence of illness because they cannot retrieve their usual support from a depleted pool. The effect of a contracting economy on the incidence of illness in populations embedded in contracting economies thereby grows beyond that expected from studies of individuals who, for example, are forced out of work.

Recent years have seen an increasing interest in the role of economic inequality on the coping process. Social reformers have traditionally drawn an analogy between income disparity and ambient pathogens such as air pollution. This disparity presumably emits a morally numbing pathogen that makes us not only less helpful to the needy, but also less willing to contribute to social support pools that include socioeconomic peers.

Contemporary reformers claim a causal chain in which widening income disparity erodes social cohesion. The loss of social cohesion makes it more difficult for everyone, not just the poor, to cope with biological and behavioral hazards. Failure to cope then manifests in illness and death itself.

The reformers' argument, although intended primarily to influence the policy debate over the

distribution of wealth, has implications for the epidemiology of stress-related illness. If income disparity weakens social cohesion, it will likely reduce the effectiveness of social support networks. Less effective social support increases the likelihood that economic and other stressors will yield illness.

The Economy's Effect on Tolerance for Coping

The economy apparently affects the diagnosis of illness by affecting community tolerance for coping. Society applies the label illness to physical and behavioral characteristics that reduce a person's ability to perform day-to-day functions. The tolerance of a community for changes in performance, therefore, becomes an important determinant of whom it judges ill.

Sociologists and psychologists report that the economy affects tolerance for deviance from performance standards. Ecological psychologists have, for example, noted that understaffed organizations (i.e., those with a high ratio of roles, or functions, to participants) tolerate poor performance by members more than overstaffed organizations. Maintaining an understaffed organization supposedly requires members to be tolerant of the shortcomings, real or imagined, of the relatively few persons available to perform needed functions. Persons in understaffed organizations whose coping strategies include physiological and behavioral adaptations that could be labeled as illness (e.g., alcohol abuse) will go undiagnosed because the label may, by rule, disqualify them from positions for which less deviant candidates cannot be found.

Overstaffed organizations, on the other hand, can choose from among many candidates for positions and can set relatively high standards for acceptable functioning. Persons adapting to stressful events may not function as well as other candidates. This performance deficit makes them the least likely to find positions. Accepting the label ill gives them a socially acceptable explanation for their lack of a position.

Economists have developed the theory of reservation wage to describe the individual choice to seek work or income transfers. The theory implies a continuum of physical and behavioral fitness among those who compete for jobs. Society decides where on this continuum it will make income transfers. If too high on the continuum, otherwise productive workers will seek transfers rather than compete for work. If too low, persons with illness will be forced to compete for jobs and become even sicker.

Wherever on the continuum political institutions draw the income transfer line, workers near it have the option of competing for jobs or seeking benefits. Economists refer to the wage at which someone no

longer competes and applies for income transfers as his or her reservation wage.

Sociologists have applied the staffing and reservation wage concepts to the community at large. A contracting economy implies relatively many overstaffed organizations, while an expanding economy implies the opposite. The fraction of the labor continuum that can exceed its reservation wage by holding a job goes up with understaffing and down with overstaffing. The number of persons seeking the label ill thereby changes with the ability of the economy to provide jobs with relatively high wages. The incidence of diagnosed illness moves inversely over time with the economy, not only because the labor market affects true incidence but also because it affects community tolerance for performance deficits.

Socioeconomic Status and Stress

The most frequently replicated findings in epidemiology include the inverse association between measures of socioeconomic status and health. Considerable controversy remains over the cause of this association. As might be expected, some argue that the relationship results from the fact that sick persons cannot compete well in the labor market with healthy persons. The argument that illness induces relative poverty justifies, in part, the extensive array of disability compensation programs in the industrial world. Ill persons unable to compete for jobs presumably need income transfers to avoid sinking into poverty.

The rival argument assumes that market economies create a distribution of income in which those with relatively little inherited wealth remain poor because gaining highly compensated skills and making investments requires wealth. Being relatively poor, moreover, means that a person can purchase relatively few of the goods and services that shelter us against stressors (e.g., decent housing in safe neighborhoods) or bolster our coping capacity (e.g., leisure, wholesome food). Being poor, therefore, increases the likelihood of becoming ill.

The relative contribution of each mechanism to the statistical association between socioeconomic status and health remains controversial. Researchers who study this issue also contribute to the economic stress literature because they document that persons most likely to avoid economic stressors also have coping assets and enjoy high community tolerance for their coping. We know from empirical study that persons with wealth suffer fewer stressful events during economic contraction than those in the middle and lower classes. It does not require empirical study to conclude that persons with more money can purchase more coping resources than can those with less

money. It also appears that physical and behavioral deviance among the poor more likely leads to being labeled ill than similar deviance among the rich. Being relatively poor, therefore, makes a person particularly vulnerable to the stressors of economic contraction.

Policy Implications and Conclusions

Any discussion of economic stressors and their effects must at least allude to economic policy because such stressors result mostly from public and private decisions regulated by political institutions. Regulatory institutions intervene in these decisions only when costs appear to exceed benefits. While researchers may study the health effects of economic perturbations to satisfy their curiosity, they typically claim that the work has applied value in that it could help regulators better account the social costs of public and private decisions. The claim implies that public policy could, indeed, should reduce the frequency or virulence of economic stressors such as job loss.

Much controversy has arisen in Europe and North America over whether regulators have gone too far or not far enough in their attempts to reduce the stress of economic change. Policies now in place appear to assume that we previously went too far and discouraged private investment by depressing the return to capital. Defenders of the current policy acknowledge that increasing the return to private investment induces economic restructuring and its attendant pain in our personal and communal experience. They predict, however, that lowering the return to investors would drive capital to less regulated and less taxed economies. This would supposedly displace more labor in the developed world than restructuring, and inflict much unregulated stress and untreated illness in developing countries.

The assumptions underlying current policy remain controversial. The epidemiology of economic stress, therefore, will likely remain an important issue in public health as well as in the debate over economic policy.

In summary, the performance of an economy can affect the health of the population it supports. Economic contraction increases the number of persons coping with undesirable job and financial events. These events increase the risk of experiencing other stressors not intuitively connected to the economy. The adverse effects of these stressors spread to family and friends.

Rapid economic growth also induces adaptations that should, according to classic theory, increase the incidence of stress-related illness. Research on work-related trauma and alcohol consumption, for example, supports this connection.

A contracting economy affects our capacity to cope with stressors. Persons who lose income cannot purchase as many coping resources as they once did. This reduces their ability to deal not only with new economic stressors but also with chronic stressors previously buffered with purchased coping resources. The tangible and intangible coping resources gotten from social networks are also more difficult to obtain when the economy contracts. This is true because there are fewer surplus resources to contribute to the common pool at the same time that there are more demands upon it.

Economic stressors can also increase the incidence of illnesses not typically thought to be stress related, because coping with such stressors can leave us with fewer resources to avoid risk factors for, or detect early signs of, illnesses unrelated to stress. The economy can, moreover, affect the tolerance of society for persons coping with stressors. We know that overstaffed communities, as indicated by high unemployment rates, reduce competition for scarce jobs by increasing the diagnosis of disability.

Economic contraction inevitably increases the number of persons who are poor. Being poor is a risk factor for stressors of all sorts and, by definition, means that access to coping resources is relatively constrained.

What Education Levels Indicate

Lower Exposure to Stressful Situations

Better Response in Stressful Situations

Higher Socioeconomic Status

Learned Effectiveness and the Sense of Control

Life-Course Compounding
Signs of Lower Stress

Glossary

<i>Acute stressor</i>	An undesirable and uncontrollable event or transition requiring personal adaptation.
<i>Chronic stressor</i>	A situation characterized by prolonged discrepancy between goals and means.
<i>Human capital</i>	Productive capacity developed, embodied, and stored in humans themselves.
<i>Learned effectiveness</i>	The ability to produce desired outcomes gained through study, practice, and experience.

<i>Resource substitution</i>	Using one thing in place of another, and finding ways to achieve ends with whatever materials, relationships, and circumstances present themselves.
<i>Sense of control</i>	A learned and generalized sense of directing one's own life, ranging by degrees from fatalism and a deep sense of helplessness to instrumentalism and a firm sense of mastery.

What Education Levels Indicate

Formal education serves three functions in modern societies: (1) developing abilities through progressive instruction and training, (2) grading individual levels of development and gating advancement, and (3) regulating access to occupations and jobs. Developed nations all measure attainment by years and degrees, in a manner increasingly comparable across nations. The years measure progressive levels, each attainable by most students within one school year of effort. The degrees certify the completion of specific multi-year programs. Education level refers both to years and degrees; it indicates the level of ability developed, the exposure to progression and selection, and the opportunities regulated as a consequence. Together these influence an individual's exposure and response to stressors throughout adulthood.

Lower Exposure to Stressful Situations

The abilities and opportunities provided by higher levels of education reduce exposure to stressful situations. Researchers generally categorize stressors as events (acute stressors) or conditions (chronic stressors.) Life-change events are transitions that require personal adaptation. They can be desirable (e.g., getting married) or undesirable (e.g., becoming widowed). They also can be controllable (e.g., quitting a job) or uncontrollable (e.g., getting fired). The more undesirable and uncontrollable the events, the more distress they produce. Higher levels of education shift the balance of events. Controllable and desirable ones become more likely; uncontrollable and undesirable ones become less likely. An event such as a job promotion produces some stress as the individual adapts to the new demands, but the positive implications moderate the stress and make it stimulating rather than disturbing. In addition, it marks a transition to new circumstances with a more favorable balance of events and greater social and economic resources. An event such as getting fired or laid off demands as much or more adaptation, but also has the demoralizing implications of inadequacy and impending hard times.

In addition, it often marks a transition into prolonged unemployment, economic hardship, family strife, lower social standing, and diminished opportunity. Those situations are stressful, and they shift the likely balance of subsequent events unfavorably.

Higher levels of education help individuals avoid chronic stressors, characterized by a prolonged discrepancy between goals and means. Chronic stressors include prolonged unemployment; economic hardship and poverty; work that is repetitious, closely supervised, or boring; neighborhood disorder and decay; unsupportive or conflict-ridden relationships; parenting with no partner or an unhelpful one; solitary caring for an aging parent or other impaired dependent; and conflicting demands of work and family.

Chronic stressors are especially harmful to emotional and physical health. Their persistence erodes emotional, physical, and social resources and discourages corrective action. For example, when people are unemployed, they need or want paid work but are not able to find an acceptable position. Being unemployed for months can use up personal and household savings. The shortage of money can lead to economic hardship, which is not being able to buy things the household needs, such as food, clothes, transportation, medicine, and medical care, and not being able to pay the rent or other bills. Repeated failures to find a job become increasingly demoralizing and discouraging. Each failure makes people's emotional need for success greater while making success on the next try seem less likely. The need for comfort and relief can encourage people to overeat sugary and fatty foods, drink heavily, abuse drugs, engage in sexual indiscretions, or escape obsessively into television, movies, novels, games, and the like. Meanwhile, the economic shortfalls get larger with time.

Supportive relationships can ease the individuals' emotional and economic strains, but they do it by spreading the burden to others. The more intense and persistent the hardship, the greater the stain put on relationships. Tensions mount, expressed in irritation, blaming, anger, and strife that may include violence. The others become unsupportive and perhaps even hostile. Relationships break up.

The higher the level of education, the less likely individuals will get into situations of chronic stress, the better they cope if in them, and the quicker they get out of or correct the situation.

Better Response in Stressful Situations

Individuals with higher levels of education respond better in stressful situations. They solve problems

better, control their neuroendocrine stress responses better, and use their mobilized energy more constructively. People with higher levels of education take a more pragmatic approach to problems, looking for solutions rather than just getting anxious, angry, or depressed. They also have greater cognitive flexibility, which is the ability to imagine and consider a variety of possible solutions or viewpoints. They are better at communicating and negotiating, have better sources of information, and have more skill at judging and applying information. These abilities make individuals more effective and also more self-assured, which reduces neuroendocrine reactivity.

Individuals with higher levels of education also make better use of the energy mobilized in the stress response. The mental and physical activity directed at problem solving helps use the energy constructively. In addition, adults with higher levels of education are more likely to have habits designed to channel the excess energy mobilized by stress constructively, such as jogging, bicycling, walking, gardening, weight lifting, swimming, playing active games such as tennis, or taking fitness classes such as aerobics or yoga.

These better events, situations, and responses associated with higher levels of education result from its two primary consequences: socioeconomic status and learned effectiveness.

Higher Socioeconomic Status

Social scientists view education level as a major element of achieved social status, along with occupational status, management level, earnings, household income, and wealth. The level of education achieved acts as a structural element of a person's life, like a structural beam in a building. Many other aspects of life depend on a person's level of education and take shape with respect to it, including the other achieved statuses. In the advanced industrial nations, education level is increasingly important to status attainment (how high a person rises socially and economically) and status transmission (how many advantages in one generation are passed to the next). Higher status gives an individual more money, authority, influence, and freedom. It shifts life events toward more controllable and desirable ones, and it reduces the risk of a prolonged or severe discrepancy between goals and means.

The higher statuses achieved through education generally reduce stress. The chief exception is managerial responsibility. Management requires a responsibility to others for the performance of others; a manager is responsible to those above for the accomplishments of those below and is responsible to those below for the rewards and resources allocated by

those above. But no one can completely control the behavior of others. This creates stress. Work organizations compensate for the stress of greater responsibility by reducing other strains on managers. Higher salaries reduce managers' household economic strains and allow the purchase of goods and services that relieve other demands on time and effort. More important, however, managers generally are given more freedom to decide what they do and how and when they do it, which reduces the stress associated with job demands. They also generally are given more resources and opportunities to do things they find challenging and interesting, which helps make job demands stimulating rather than distressing.

Learned Effectiveness and the Sense of Control

During the twentieth century, formal education came to be viewed as a system for developing human capital. Economists had long viewed capital as material wealth in the form of money or property that is or can be used to produce more material wealth. However, the growth of wealth in the United States and other nations exceeded what could be attributed solely to accumulating monetary and physical capital. Economists revived Adam Smith's concept of human capital as productive capacity developed, embodied, and stored in humans themselves. Levels of formal education are the most important measure of human capital, along with work experience. Formal education develops the skills and abilities of general productive value (such as reading ability or punctuality), as distinct from ones of value in a particular job (such as knowing which forms to fill out or how to operate a particular machine).

Education reduces stress partly by enhancing material productivity but mostly because it develops general problem-solving abilities. The learned effectiveness makes people better at avoiding or solving problems and more confident, reducing stress throughout life. Formal education teaches people to learn. It develops the skills and habits of communication: reading, writing, inquiring, discussing, looking things up, and figuring things out. It develops analytic skills of broad use such as mathematics, logic, and, on a more basic level, observing, summarizing, synthesizing, interpreting, and experimenting. The more years of schooling, the greater the cognitive development, characterized by flexible, rational, complex strategies of thinking. Education teaches people to think logically and rationally, see many sides of an issue, analyze problems, and design strategies of personal action.

Education also develops broadly effective habits and attitudes such as dependability, good judgment,

motivation, effort, trust, and confidence. It instills the habit of meeting problems with attention, thought, action, and persistence. In school, people encounter and solve problems that are progressively more difficult, complex, and subtle. This process develops persistence and self-assurance as well as skill.

When individuals control their own lives, this means they exercise authority and influence over it by directing and regulating it themselves. People vary in the control felt over their own lives. Some feel they can do just about anything they set their minds to. They see themselves as responsible for their own successes and failures and view misfortunes as the results of personal mistakes. Others feel that any good things that happen are mostly luck – fortunate outcomes they desire but do not design. They feel personal problems mostly result from bad breaks or the callous selfishness of others and feel little ability to regulate or avoid the bad things that happen. The sense of control varies by degree, ranging from fatalism and a deep sense of helplessness to instrumentalism and a firm sense of mastery.

The sense of personal control is a learned and generalized expectation. As such it acts as a cognitive-behavioral accumulator, integrating past experience and bringing it into the present. In many ways, a sense of control is to successful action as wealth is to profitable investment – an accumulated product returning subsequent advantage. Perceptions of control grow out of the interaction between intention and outcome. The occurrence of something desired, planned, or attempted reinforces a sense that individuals' choices and actions have consequences. This, in turn, encourages attention to setting goals, directing actions toward the goals, evaluating apparent consequences, and revising efforts.

The sense of control is more than seeing things occurring as individuals want. It is individuals seeing themselves as the authors and editors of the choices and actions that link their preference to occurrence. Within contexts that support its success, critical self-direction sharpens their ability and encourages effort. The resulting effectiveness and resilience strengthen the sense of control in a beneficial developmental spiral. The system of formal education serves as the chief social institution for developing this sense of control.

A number of social and behavioral sciences recognize the importance of a sense of personal control. The concept appears in a number of related forms with various names, including internal locus of control, mastery, instrumentalism, self-efficacy, and personal autonomy; at the other end of the continuum (lack of control), this is fatalism, perceived helplessness, and perceived powerlessness. A low or negative

sense of control corresponds to learned helplessness, a behavioral state of suppressed attention and action that induces biological stress in mammals.

Life-Course Compounding

Many things in life produce effects that fade over time as individuals adjust to their circumstances, tastes and times change, enthusiasms wane, and new experiences intervene. Education's effects work the opposite way, growing with time. Education transforms people, putting individuals' lives on a different track. Because education develops resources that inhere in people, its consequences are present in all aspects of life throughout their entire lifetime. Education affects virtually all aspects of life, including habits, interpersonal relationships, family responsibilities, occupational exposures and opportunities, economic sufficiency and security, neighborhood qualities, autonomous and creative activities, and people's sense of controlling their own lives.

Education tends to speed or advance beneficial accumulations and to slow or delay detrimental ones. The consequences accumulate on many levels. They include job security, pay level, occupational status, and wealth on the socioeconomic level; habits such as exercise or smoking or relationships such as marriage on the behavioral level; body mass, atherosclerosis, or hippocampal mass on the anatomic level; aerobic capacity and blood pressure on the physiological level; and glucose tolerance or mitochondrial damage on the intracellular level. Undesirable accumulations typically can be reversed, even after a crisis, but generally only over a period of time as a result of concerted and multifaceted effort. Education helps individuals to avoid undesirable accumulations that need correction, to correct undesirable accumulations before they precipitate a crisis, and, failing that, to heed the implications of the crisis and take the difficult but necessary corrective action.

Many of education's consequences influence one another or regulate one another's effects. The feedback among accumulators amplifies the long-term effects of unchanging attributes such as sex, race, and year of birth and of persistent ones such as occupation and wealth. It also amplifies the effects of short-term random shocks to each accumulator.

Education makes individuals more adept at resource substitution (using one thing in place of another) and finding ways to achieve ends with whatever materials, relationships, and circumstances present themselves. Higher education makes individuals better at acquiring whatever they need and better at using whatever they find available. As a result, more education tends to increase an individual's store of

the society's standard resources while improving the individual's ability to improvise resources. A greater capacity for resource substitution makes the absence of any one standard resource less harmful for the better educated. Conversely, less education leaves individuals less adept at acquiring and inventing resources, increasing the individuals' dependence on any standard resource they have.

Stressors often occur in cascading sequences. The relative lack of resources and resourcefulness among the poorly educated exacerbates the outcomes at each step. Ineffective individuals often move through a cascading sequence of corrosive situations made worse at each step by the predisposing traits and conditions that led to those situations. The capacity for resource substitution helps the better educated to avert problems or ameliorate outcomes at each step.

Signs of Lower Stress

A variety of observations indicate that people with higher levels of education generally have lower levels of stress. They encounter fewer undesirable events and situations, as summarized earlier. They also report fewer of the symptoms and health consequences of stress. They report fewer signs of autonomic arousal such as sweaty palms, queasy stomach, dry mouth, faintness, or short of breath and a racing heart when not exercising or working hard. They report fewer days of feeling worried, anxious, and tense. They also report less hostility and anger toward others. (However, when worried, anxious, or tense, they are more likely to report anger along with it.) The better educated have fewer symptoms of depression such as feeling sad, lonely, or worthless and being sleepless, listless, or unable to face the day. They have fewer stress-related health conditions such as high-blood pressure, poor blood sugar control, or frequent colds and influenzas; fewer of the stress-related diseases such as coronary artery disease or type 2 diabetes; and fewer of the stress-related medical crises such as heart attack or stroke.

The better educated have lower scores on bio-marker indexes of allostatic load, which is the cumulative biological degradation from stress. There are two kinds of markers. One set measures blood, urine, or saliva levels of the hormones involved in the stress response, such as high overnight urinary excretion of cortisol, epinephrine, and norepinephrine and low serum dihydroepiandrosterone sulfate (DHEAS). The other set measures the cumulative effect of exposure to those hormones, such as high plasma levels of glycosylated hemoglobin (indicating chronic poor blood sugar control), high systolic and diastolic

blood pressure, high serum levels of total and of high-density cholesterol, high waist-to-hip ratio (measuring central adiposity), low serum albumin and high fibrinogen and C-reactive protein (indicating chronic inflammation), and indicators of impaired organ function such as low creatinine clearance in the kidneys and low peak air flow in the lungs. Differences in allostatic load scores predict mortality risk in older Americans and statistically account for approximately one-third of the differences in mortality risk across degree levels of education.

Theory
Research Evidence
Implications for Intervention

Glossary

<i>Contract</i>	An agreement that defines a norm of equivalence by specifying obligations, benefits, rights, and duties in interpersonal exchange (e.g., work contract).
<i>Overcommitment</i>	A motivational pattern of work-related striving toward high achievement that is associated with increased health risks in the long run.
<i>Prediction error theory</i>	A theoretical model developed in neuroscience to predict neural activation and deactivation in relevant areas of the brain according to the principles of economy and learning.
<i>Social reciprocity</i>	A fundamental principle of social exchange that guarantees equivalence of give and take between two individuals or parties.
<i>Social role</i>	A set of expectations or norms (duties and options) directed toward people who hold important social positions (e.g., work role, family role, and volunteer role).

Theory

One of the important tasks of medical sociology consists in explaining how the social environment affects human health. Theoretical models are instrumental in identifying those aspects within the complex social reality that accounts for increased or reduced health risks in populations. These models are then translated into measures with the help of social science research

methods that meet the criteria of adequate reliability and validity and are tested in the framework of epidemiological or experimental study designs.

One such model, labeled effort–reward imbalance, is concerned with adverse effects on health produced by the violation of one of the fundamental, evolutionarily stable principles of human societies – social reciprocity. According to this principle, any action or service provided by person A to person B that has some utility to B is expected to be returned by person B to A. Exchange expectancy does not implicate a full identity of the service in return, but it is essential that this activity meet some agreed-on standard of equivalence. To secure equivalence of return in crucial transactions, social contracts have been established as a universal societal institution. A contract defines a norm of equivalence by specifying obligations, benefits, rights, and duties in interpersonal exchange. Trade, work and employment, marriage, and intergenerational transfer are examples of contractual exchange. These contracts may vary considerably according to the specificity of their regulations, the sanctions expected in case of deviance, or the time frame of exchange. Yet, in all instances, contracts are instrumental in providing members of a society with a sense of security by creating trust. Trust is a mental state motivating people to engage in social exchange even if the trade-off is highly uncertain. Expectancy of reciprocity is the driving force of trust.

The principle of reciprocity not only is rooted in human evolution, but plays a significant role in ontogenesis as well. Research on attachment formation in infancy has demonstrated the importance of reciprocal exchange between infant and caregiver in early postnatal life as one of the preconditions of normal human development. For these reasons, breaking the norm of reciprocity in contractual exchange is expected to have adverse consequences for the health and well-being of disadvantaged people.

The model of effort–reward imbalance states that recurrent or long-lasting nonreciprocity in contractual

exchange increases the risk of stress-related disorders in exposed people, due to the powerful role of this evolutionarily old grammar of interpersonal cooperation. This model has been developed and tested with regard to work and employment, and more recently has been expanded to less formalized types of contractual exchange, in particular marital or partnership relationship, exchange between parents and children, and voluntary work.

The principle of social reciprocity lies at the core of the employment contract, which defines distinct obligations or tasks to be performed in exchange for equitable rewards. Yet, according to the effort–reward imbalance model, nonsymmetric contractual exchange is expected to occur frequently under specific conditions (see [Figure 1](#)). In this case, high efforts spent at work are not reciprocated by equitable rewards in terms of money, esteem, and career opportunities, including job security. The model of effort–reward imbalance claims that lack of reciprocity between the costs and gains (i.e., high-cost, low-gain conditions) elicits strong negative emotions with a special propensity to sustained autonomic and neuroendocrine activation and their adverse long-term consequences for health.

There are three important conditions that increase the probability of recurrent effort–reward imbalance at work: dependency, strategic choice, and overcommitment. Dependency reflects the structural constraints observed in certain types of employment contracts (e.g., unskilled or semi-skilled workers and elderly employees) when no alternative choice in the labor market is available. In modern economies characterized by a globalized labor market and organizational downsizing, the lack of an alternative choice of workplace is relatively frequent.

Figure 1 The model of effort–reward imbalance at work. Modified from Siegrist (1996).

In strategic choice, people accept high-cost, low-gain conditions of their employment for a certain time, often without being forced to do so, because they tend to improve their chances of career promotion and related rewards at a later stage. This pattern is frequently observed in early stages of professional careers and in jobs that are characterized by heavy competition.

The third condition, overcommitment, reflects the psychological reasons for a recurrent mismatch between efforts and rewards at work. People characterized by the motivational pattern of excessive work-related overcommitment may strive toward continuously high achievement because of their underlying need for approval and esteem at work. Although these excessive efforts often are not met by adequate rewards, overcommitted people tend to maintain their level of involvement. Work-related overcommitment is elicited and reinforced by a variety of job environments and is often experienced as self-rewarding over a period of years in occupational trajectories. However, in the long run, overcommitted people are susceptible to exhaustion and adaptive breakdown.

In summary, the model of effort–reward imbalance at work maintains that nonreciprocal contractual exchange is frequent under these structural and personal conditions, and that people experiencing dependency, strategic choice, or overcommitment, either separately or in combination, are at elevated risk of suffering from stress-related disorders.

Research Evidence

Several sources of information on the associations between nonreciprocal contractual exchange and health are available, such as data from cross-sectional and case-controlled studies, from prospective epidemiological observational investigations, from studies using ambulatory monitoring techniques or experimental designs, and from intervention trials. The prospective epidemiological observational study is considered a gold standard approach in this field because of its temporal sequence, its sample size, and the quantification of the subsequent disease risk following exposure.

Up to now, the model has been tested in approximately a dozen prospective epidemiological reports and, in addition, in many cross-sectional and case-controlled studies. Associations of either the full model or its main components with increased health risks were found in a majority of these studies. The relatively strongest and consistent effects concern cardiovascular diseases – effort–reward imbalance at work is associated with a doubling of risk over a mean

8-year observation period. In addition, nonreciprocity at work increases the probability of suffering from depression, psychosomatic symptoms, sickness absence, and poor self-rated health. With respect to health-adverse behaviors, and especially the intensity of daily cigarette smoking, alcohol dependence, and weight gain, associations with effort–reward imbalance at work were observed more consistently in men than in women. In addition to health-adverse effects, this type of chronic stress at work increases the likelihood of changing or giving up one's job, of retiring prematurely, and, according to first results, of deviating from regulations at work.

In summary, there is solid evidence indicating that failed reciprocity in a core social role, the work role, represents an independent risk factor for a variety of highly prevalent diseases. Moreover, it undermines work-related motivations and behaviors. Results are derived from a wide range of different occupations and professions, and they concern both genders, although, in general, the effects are stronger in men. In several studies, this imbalance was found to be more frequent among lower socioeconomic groups, and its effects on health are generally stronger in these groups.

So far, the bulk of evidence comes from investigations conducted in Europe, the United States, and Canada. Given the fact that the norm of contractual reciprocity is rooted in human evolution, we would expect recurrent violations of this norm to have similar effects on health across societies and cultures. According to recent studies, effort–reward imbalance at work is associated with several indicators of reduced health in Asian countries such as China, Taiwan, and Japan.

An additional line of research is devoted to the study of nonreciprocal exchange in marital or partnership relationships, in relationships between parents and children, and in other types of cooperative activities, such as voluntary work. The recurrent experience of effort–reward imbalance in these types of social exchange was found to reduce mental health and well-being in exposed people.

What are the neural and physiological correlates of the recurrent experience of effort–reward imbalance? Several studies investigated heart rate, heart rate variability, and blood pressure during work and non-work days, using ambulatory monitoring techniques. In general, cardiovascular activity differed between employees scoring high on measures of effort–reward imbalance and those with low scores on these measures. One study, in addition, assessed salivary cortisol excretion and found a higher mean level in employees with high scores on the scale measuring work-related overcommitment.

The neural correlates of reward frustration are still poorly understood. Yet, in an investigation using functional magnetic resonance imaging with a monetary reward paradigm, neural activation in reward-sensitive prefrontal mesolimbic dopamine projection sites was not reduced when expected rewards were frustrated in otherwise healthy subjects with an extensive history of work-related effort–reward imbalance. This was different in subjects without chronic stress experience, in whom activation in these areas was reduced, as hypothesized by the prediction error theory.

Implications for Intervention

Measures to improve the balance between effort and reward and, hence, to improve reciprocity and contractual fairness at work can be implemented at three levels. The first level relates to the individual worker. Increasing awareness of failed reciprocity at work among employees, informing them about possible health effects, and providing cognitive-behavioral interventions in high-risk groups to reduce the intensity of stressful experiences (relaxation response, stress inoculation, self-instruction, and reducing high levels of overcommitment) are examples of this approach.

A related second level of health promotion at work, the interpersonal level, concerns training in leadership skills, the improvement in the handling of conflicts, or the improvement of communication and cooperation in everyday work settings. Providing appropriate esteem and recognition was shown to be an important component of the balance between effort and reward at work, and this target can be met by focused leadership training.

However, to produce a lasting impact, these human-relations measures need to be supplemented by evidence-based organizational and structural changes in the work environment. Such changes concern the division of work; its quantity and quality; work schedules and their flexibility; monetary incentives; tailored promotion opportunities, including investment in training and requalification on the job; and, most important, enhanced job security. The probability that these and related measures are realized will increase with available evidence of the economic benefits for companies and organizations that invest their increased efforts into health-promoting quality of work. Such measures are not limited to paid work, but may be extended to other types of contractual social exchange, in particular voluntary work. In conclusion, it remains to be seen how this new scientific evidence can be transferred into health-promoting policy measures that diminish the burden of societal stress.

Demographics of Elder Abuse

Characteristics of the Abused

Characteristics of the Abuser

Theories about the Cause of Elder Abuse

Institutional Abuse

Signs and Symptoms of Elder Abuse

Glossary

<i>Domestic elder abuse</i>	The abuse of an elderly person by someone closely associated within that elder's home or by somebody in the home of the person caring for that elder.
<i>Elder abandonment</i>	The desertion or willful forsaking of an elder by any person having the care or custody of that elder under circumstances in which a reasonable person would continue to provide care.
<i>Elder neglect</i>	The failure of a caregiver to fulfill his or her obligation or duty to care for an elder.
<i>Elder self-abuse</i>	A neglectful or abusive behavior by an elder that is dangerous to his or her own safety or health.

Financial elder abuse

Any theft or misuse of an elder's financial funds, property, or other resources by a person in a position of trust with an elder.

Institutional elder abuse

The abuse that occurs by paid staff in establishments designated to care for the elderly, including foster homes, group homes, and nursing homes.

Physical elder abuse

The willful infliction of physical force against an elder that results in tangible injury, pain, or impairment by a person who cares for or has custody of or who stands in a position of trust with that elder.

Psychological elder abuse

The deliberate infliction of mental or emotional suffering upon an elder by use of insults, humiliation, intimidation, threats, or other verbal or nonverbal abusive conduct.

Sexual elder abuse

The nonconsensual sexual contact of an elderly person.

Demographics of Elder Abuse

In the United States, the National Center on Elder Abuse reported that nearly 400 000 adult/elder abuse reports were investigated by Adult Protective Services in 2000. Of these, 48.5% were substantiated by Adult Protective Services. The majority of reports involved the domestic setting (60.7%), with only 8.3% occurring in the institutional setting. Perpetrators were most commonly family members (61.7%), especially spouses or intimate partners (30.2%) and adult children (17.6%). Evidence points toward the validity of the iceberg theory of elder abuse, which states that

only the most visible types of elder abuse and neglect are reported to official sources (e.g., Adult Protective Services) and that a large number of other incidents are unidentified and unreported.

Characteristics of the Abused

Women are disproportionately victimized, representing two-thirds of the victims of physical abuse, three-fourths of the incidents of psychological abuse, and greater than 90% of the cases of financial abuse. Elderly living alone have lower rates of abuse than elderly living with other persons. Increasing age is associated with a higher incidence of abuse and neglect. Elderly in poor health are nearly four times more likely to be abused than comparably aged elderly in good health. The elderly who are widowed, divorced, or never married are less likely to be abused.

Characteristics of the Abuser

Men are slightly more likely than women to abuse elders. Approximately 90% of alleged elder abusers are related to their victims. The majority of perpetrators of elder abuse are either the elder's spouse or adult children. Since families are frequently the primary caregivers for elderly relatives in domestic settings, the fact that family members are the primary perpetrators of elder abuse is not surprising. Most elder abusers are younger than their victims. This fact is most striking in the area of financial abuse, where nearly half of the abusers are 40 years old or younger.

Theories about the Cause of Elder Abuse

Numerous studies have examined the possible etiologies of elder abuse. Although the causes of most cases of elder abuse are multifactorial, six widely accepted theories have been reported in the literature.

Psychopathology in the Abuser

The psychopathology of the abuser theory focuses on the abuser's mental derangement as the primary cause of elder abuse. Specific conditions, such as psychiatric illness, alcohol and drug addiction, dementia, and mental retardation, lead to inadequacy in the abuser. As a result, the abuser is unable to positively relate to the elder. This subsequently leads to the abuse. Approximately 30% of abusers have documented psychiatric illness, and nearly 40% have a history of substance abuse.

Transgenerational Violence

According to the transgenerational violence theory, the abuser learns abusive behavior from other family

members, and this dysfunctional behavior is passed from one generation to the next. A cycle of violence then ensues. For these families, violence is perceived as a normal behavior pattern. For example, a person who was abused as child becomes the abuser when his or her parents become elderly and more dependent. Child, spouse, and elder abuse may be seen in these extended families.

Caregiver Stress

The caregiver stress theory emphasizes the stress of the abuser as the predominant factor that leads to elder mistreatment. The obligations associated with providing care for the elderly may place overwhelming demands on providers. Frequent falls, wandering, incontinence, disrobing, and verbal abuse by elders are examples of occurrences that place undue stress upon the caregiver. External stresses upon the caregiver (e.g., unemployment, personal illness, and financial hardship) may lead to his or her lashing out at the elder in frustration. A good relationship between the caregiver and the care recipient prior to illness and disability has been shown to minimize stress, even in the face of heavy caregiver demands.

The Web of Dependency

The web of dependency theory suggests that the frailty of an elder in and of itself is a cause for abuse and neglect. Increasing physical and mental impairment in the elder leads to an increasing dependency on a caregiver for the activities of daily living. As the caregiver's obligations increase, the burden and stress on him or her is also increased. As a result of this increased dependency, abuse occurs. Greater impairment and subsequent dependency of the elder may also diminish his or her ability to defend him- or herself from abuse or to escape the situation.

Caregiving Context

The caregiving context theory places emphasis on the situation of the caregiving. Elderly who are socially isolated are more prone to be abused. Families in which abuse occurs remain secluded to avoid detection. Elderly who share living space with their caregiver are also more prone to be abused. Tensions and daily conflicts are more difficult to avoid when the parties live together.

The Sociocultural Climate

Cultural and ethnic diversity may influence the prevalence of abuse. In cultures in which elders are highly esteemed or in which a strong value is placed on

Table 1 Possible signs of elder abuse and neglect

<i>Physical abuse</i>	<i>Physical neglect</i>	<i>Sexual abuse</i>	<i>Emotional abuse</i>
Bruises Unexplained In various stages of healing In regular patterns In shape of the article used Bite marks In an unusual location	Consistent hunger Poor hygiene Inappropriate dress Soiled clothing Weight loss Dehydration Urine burns Pressure sores	Difficulty walking Difficulty sitting Genitalia itching/pain Bruised/bloody genitalia Bruises around breasts Vaginal bleeding/tears Anal tears/bruising Stained/bloody underwear Sexually transmitted diseases	Habit disorder Sucking Biting Rocking Conduct disorder Antisocial Destructive Neurotic traits Sleep disorders Speech disorders Inhibition of play Psychoneurotic reaction Hysteria Obsession Compulsion Phobias Hypochondria
Burns In the shape of cigarette/cigar Immersion burns Patterned burns (e.g., from an iron) Rope burns Caustic burns	Over- or undermedication Hypothermia Lice Lack of functional aids, e.g., glasses, dentures, hearing aids, walking aids		
Fractures Unexplained In various stages of healing Multiple Spiral			
Lacerations Unexplained In an unusual location			
Internal injuries			

Table 2 Signs of financial or material exploitation

Abrupt changes in a will or other financial documents
Inclusion of additional names on an elder's bank signature card
Unauthorized withdrawal of funds from an elder's financial account
Unexplained disappearance of money or other valuables
Forging of an elder's signature for financial transactions
Sudden appearance of previously uninvolved relatives claiming rights to an elder's possessions
Sudden transfer of the elder's assets to another individual
Unnecessary services being rendered by an elder (such as unnecessary home improvements)
Unpaid bills or inability to purchase basic provisions despite availability of adequate financial resources
Sudden changes in a financial account or the banking practice of an elder
Elder's report of financial exploitation

family responsibility, caring for an elder member of the family is expected. Failure to fulfill this caregiver role may cause shame and frustration. Cultural sanctions against revealing family problems to outsiders may subsequently prevent families from seeking help. If a family has relocated to a foreign country, adaptation to that culture may create additional stress and conflict as to how to care for their elders.

Institutional Abuse

Abuse occurs not only in domestic settings, but also in institutions such as nursing homes, mental institutions, and adult foster homes. At least half of all

nursing home patients suffer from some form of dementia or mental illness. This group of patients is more prone to be abused and is less likely to report the abuse. In institutional settings, physical elder abuse has been reported to occur in one-third of patients, with psychological abuse occurring in up to 80% of elders. The causes for this abuse in institutions are multifactorial. The lack of understanding of the cause of the elder's behavior, dissatisfaction among the institution's staff, patient-staff conflict, and burnout among staff have been cited as causes for institutional elder abuse. Education of the staff is the most important factor to decrease elder abuse in institutions. In addition, more psychiatric services need to be provided for elders residing within institutions.

Signs and Symptoms of Elder Abuse

The signs and symptoms of elder abuse can range from subtle to grossly apparent. Professionals who routinely work with the elderly are typically not well trained in evaluating signs and symptoms of elder abuse. As a result of this lack of training, an underreporting of abuse has been clearly documented. Possible signs and symptoms of elder abuse are demonstrated in [Table 1](#). Elder abandonment also occurs and can manifest as the desertion of an elder at a hospital, nursing facility, shopping center, or other public location. Financial or material exploitation can manifest in a number of ways, with examples given in [Table 2](#).

Self-neglect is difficult to determine, and, depending on where the elder lives, specific laws exist pertaining to when the elder's self rights become superseded by the government. Signs of self-neglect include unsanitary living conditions (e.g., animal or insect infestation, no functioning toilet, fecal or urine smell), hazardous living quarters (e.g., improper wiring, no heat or running water), inappropriate or inadequate clothing, lack of necessary medical aids (e.g., eyeglasses, hearing aids, dentures), grossly inadequate housing or homelessness, poor personal hygiene, and improperly attended medical conditions. Social workers, the medical profession, law enforcement, and the general public must be educated to increase awareness and thereby decrease the occurrence of elder mistreatment.

Introduction

Methodology

Biological Mechanisms

Psychological Applications

Glossary

Electrodermal lability

An individual difference dimension of electrodermal activity. High labile individuals tend to demonstrate greater rates of nonspecific responses and may also have higher skin conductance levels and slower habituation rates.

Habituation

The process whereby the repetition of discrete stimuli leads to the decline in response amplitude or occurrence of electrodermal responses to successive stimulus presentations.

Nonspecific responses

Frequency counts of spontaneous or nonspecific responses (e.g., nonspecific skin conductance responses), which occur in the absence of external stimulation. Rates of nonspecific responding are said to reflect individual differences in electrodermal arousal levels and may also be related to task demands for energy mobilization, together with responses to internally mediated thoughts or emotions.

Phasic responses and tonic levels

Phasic responses consist of short-lived changes in electrodermal activity (EDA) elicited by discrete external stimuli and are characterized as either skin conductance responses (SCRs) or skin resistance responses (SRRs). Tonic levels are longer-term absolute measures of either skin conductance level (SCL) or skin resistance level (SRL). Typical ranges are 0.05–0.5 μS for SCR and 1–30 $\mu\text{S}/\text{cm}^2$ for SCL.

Skin conductance (SC) and skin resistance (SR)
Sweat glands

Units of electrodermal activity, which are expressed in either conductance (microsiemens or micromhos) or resistance (micro-ohms).

Two types of sweat gland are located under the skin surface: the apocrine

glands, which are usually associated with the hair follicles and distributed around the axilla and pubic regions, and the eccrine glands, which are widely distributed over the body surface and serve a thermoregulatory function. However, the latter are also more closely distributed (approximately 1000 glands/cm²) on the palms of the hands and the soles of the feet and are sympathetically innervated.

Introduction

At the turn of the nineteenth century, several researchers (e.g., Féré and Tarchanoff) demonstrated changes in the electrical resistance of the skin, which were elicited by either sensory or emotional stimuli. With the advent of electronic amplification and recording equipment in the mid-twentieth century, electrical recording from the skin as a correlate of psychological activity was becoming a common measure within psychological research. Early psychological researchers such as Darrow investigated the mechanisms underlying electrodermal responding, together with its psychological correlates. The use of the galvanic skin response as a measure of classical conditioning or psychological stress and arousal received widespread acceptance within the 1960s. There followed a period of consolidation whereby the appropriate methodologies were standardized and models of electrodermal responding were elucidated. Alongside other noninvasive measures of autonomic activity such as heart rate and blood pressure, electrodermal measures were commonplace within psychophysiological publications.

Electrodermal responses are frequently interpreted as reflecting changes in attention since they are considered major components of the orienting response. More generally, measures of electrodermal activity (EDA) are considered as reflecting changes in autonomic reactivity elicited by psychosocial events associated with emotion, task demands, motor responding, workload, stress, etc. Although contemporary psychophysiological research tends to rely more on centrally derived measures such as evoked potentials or brain imaging, peripherally recorded autonomic measures such as EDA still have their place as sensitive and noninvasive physiological indices of psychological processes and states. Finally, it should be acknowledged that there are a range of nonelectrical methods for quantifying sweat gland activity. One such method is the Palmar Sweat Index, which consists of taking an imprint of the

skin in order that the frequency of active sweat glands can be identified; it has frequently been used by stress researchers.

Methodology

Recording Techniques

There are a number of electronically derived measures of EDA, which can be obtained from the skin surface depending on the design and characteristics of the recording amplifiers. First, endogenous skin potentials (SPs) can be recorded directly using an appropriate amplifier and recording electrodes. This technique is referred to as endosomatic EDA. In contrast, exosomatic EDA consists of changes in an externally applied voltage or current, which is impressed through the skin via a pair of bipolar recording electrodes. The most common techniques rely on direct current (DC) measurement and consist of either measuring changes in conductance by keeping the voltage constant or changes in resistance by keeping the current constant. Alternatively, skin impedance may be measured using alternating current (AC). The most widely accepted technique is the measurement of skin conductance using a constant voltage applied between the electrodes of around 0.5 V. The techniques may also be applied outside of laboratory situations using ambulatory methods. More recently, circuits have been designed to measure EDA concurrently with brain imaging equipment and techniques.

The preparation of the skin surface and placement of electrodes are important methodological considerations. Since only some skin areas contain eccrine sweat glands that are psychologically reactive, EDA tends to be restricted to the palmar surfaces of the hands, and in particular, to the first and second fingers of the nondominant hand. In order to record EDA, specifically prepared electrodes (usually silver/silver chloride) need to be fixed in pairs to the skin and used in conjunction with specially made electrolytes. Researchers wishing to use EDA need to pay particular attention to published accounts of standardized procedures.

The recorded signal, whether it is conductance or resistance, is either displayed using a chart recorder or digitally sampled using an analog-to-digital converter and computer. Care should be taken to ensure that sufficient amplification and digital sampling rates are employed, so that the overall conductance level can be assessed, together with sufficient resolution so that phasic fluctuations can also be discriminated. In the case of traditional amplifiers and chart recorders, this will necessitate the use of a device that backs off a

calibrated proportion of the skin conductance level prior to high gain amplification.

It is essential that any research intended for publication and using electrodermal measures strictly conforms to published methodological guidelines.

Quantification

Electrodermal activity is usually expressed in conductance units (microsiemens or micromhos), even if a measure of skin resistance was originally obtained (i.e., conductance = $1/\text{resistance}$). Researchers usually discriminate between tonic and phasic electrodermal measures. Tonic measures refer to long-term fluctuations in EDA and are best characterized by changes in skin conductance level (SCL) and the frequency of nonspecific or spontaneous fluctuations (see Figure 1). They are brief changes in EDA that are not specifically elicited by external stimuli but that arise due to internal thoughts, situational demands,

emotional states, and individual differences in electrodermal lability. In contrast, phasic measures are specific skin conductance responses (SCRs), which have been elicited by an identified and usually externally presented stimulus. Phasic SCRs are usually quantified as an amplitude change from a baseline level value (prior to presentation of a stimulus) to the peak of the response (see Figure 1). In addition to amplitude measures, temporal indices such as response latency, rise time, and half-recovery time may also be assessed. Skin conductance responses are frequently obtained within what is known as an habituation paradigm, whereby simple sensory stimuli are presented to the participant and the autonomic responses measured to subsequent repetitions. When habituation paradigms are used, further measures of change in response amplitude across successive trials are also calculated using regression techniques.

Prior to analysis, electrodermal data are frequently transformed in order to achieve more normally distributed samples for parametric statistical analysis. There also exists a statistical dependency between phasic response amplitude and individual differences in tonic levels. Researchers will frequently use a variety of statistical transformations (e.g., log. and ratio measures) and range-correction methods to adjust for this response level dependency, which is sometimes termed the Law of Initial Values.

Biological Mechanisms

Fluctuations in either conductance or resistance have been attributed to variations in sweat gland activity. Essentially, alterations in conductance of the sweat gland are said to arise from a variety of different mechanisms involving changes in both sweat conductivity and physical level of sweat within the duct. The former is said to be associated with an active ionic reabsorption membrane located within the duct wall, and the latter with the mechanical extrusion of sweat from the gland. From a psychological perspective, the most important influence on sweat gland activity is through the autonomic cholinergic innervation to the glands. A variety of brain regions are implicated in the central control of EDA, including the lateral frontal and dorsolateral cortex, together with various cortico-limbic connections including the anterior hypothalamus and anterior limbic and infralimbic cortices. More recently, several brain-imaging studies have been conducted that looked at the functional location of EDA. These studies suggested separate mechanisms for the maintenance of electrodermal level and the activation of responses.

Figure 1 Schematic representation of skin conductance activity. Three individual skin conductance curves are represented with differing skin conductance levels and numbers of nonspecific responses (ns). Inset displays enlarged skin conductance response to specific stimulus (shaded block) and indicates (a) response latency, (b) response rise time, (c) response half-recovery time, and (d) response amplitude.

Psychological Applications

Attention and Information Processing

Phasic measures of EDA are frequently adopted as indices of attention and information processing. Skin conductance responses obtained within habituation and classical conditioning paradigms are interpreted in terms of the orienting response. Variations in SCR amplitudes are associated with changes in stimulus intensity, novelty, and significance. According to Ohman, the presence of an SCR indicates that a novel or significant stimulus has been detected by the information processing system and that a call has been made for further controlled processing of the incoming stimulus. The sizes of SCR amplitudes, therefore, are frequently interpreted as measures of attention.

Emotion

Attempts have been made to interpret SCRs with respect to either attentional or emotional responding. Lang and colleagues have argued, however, that whereas other peripheral psychophysiological measures such as heart rate, potentiated startle, and electromyographic activity might distinguish between the positive and negative aspects of emotional experience, SCRs appear sensitive only to the intensity or arousal dimension and not to the direction or valence of the emotion involved.

Stress

Both phasic and tonic measures have been argued to reflect peripheral arousal responses to stressful stimuli. In particular, EDA is said to be sensitive to psychosocial aspects of social interactions, workload, and occupational strain and has also been argued to reflect changes in anxiety. As well as the amplitude of SCRs, increases in the absolute SCL and the frequency of nonspecific response are often interpreted as reflecting increasing response to stress. Indeed, it is argued that a reliable individual difference dimension known as electrodermal lability might moderate the relationship between autonomic arousal and psychosocial influences. Similarly, EDA is frequently assessed in studies of psychopathology and has been widely investigated in clinical populations, including depression, anxiety, schizophrenia, hypertension, and diabetes.

Recognition of the Problem

Predictors

Biological Factors

Interventions

Glossary

<i>Acute stress disorder</i>	A mental disorder involving anxiety, dissociation, and reexperiencing that leads to clearly impaired functioning; arises after exposure to a traumatic stressor in a 1-month time frame.
<i>Compassion fatigue</i>	The reduction of empathy and presence of burnout in helpers who have been overexposed to the suffering from traumatic stressors of others.
<i>Debriefing</i>	An intervention conducted soon after exposure to a traumatic stressor, in a group or individually, designed to lessen the psychological impact of the event on future functioning.
<i>Hippocampal volume</i>	An index of the size of a brain structure involved in both stress response and memory processes as measured by magnetic resonance imaging.
<i>Hypothalamic-pituitary-adrenal (HPA) axis</i>	The hormone system in the body, comprising the hypothalamus and the pituitary and adrenal glands, that regulates many basic functions, including the fight-or-flight response.
<i>Peritraumatic dissociation</i>	The experience of altered time sense, altered sense of self, or altered sense of place during and immediately following exposure to a traumatic stressor.
<i>Posttraumatic stress disorder (PTSD)</i>	A mental disorder involving the reexperiencing and avoidance of aspects of a traumatic stressor, accompanied by symptoms of increased arousal occurring at least 1 month after traumatic exposure.
<i>Routine occupational stressors</i>	The nontraumatic events that derive from organizational forces or other aspects of emergency work, such as contact with the public or lack of necessary equipment.

Traumatic stressor

The occurrence of an event that involves the actual or threatened death or serious injury or the threat to the physical integrity of oneself or a family member as either a victim or as a witness.

Exposure to traumatic stress in emergency personnel follows from the nature of the work, being primarily involved with witnessing or being the potential victim of serious injury, death, or threat to physical integrity and frequently involving danger, sometimes potentially lethal, to oneself. The stress reaction is similar to that of other groups exposed in this way, such as soldiers in combat, and can include the reexperiencing of the traumatic event, avoidance and numbing, and manifestations of hyperarousal such as sleep disturbance, impulsive anger and irritability, trouble concentrating, or hypervigilance. Although the response may be moderated or may habituate after simulations in training or repeated exposures over the course of years on the job, it does not seem to disappear. First-responders typically include police, firefighters, ambulance personnel, search-and-rescue teams, and the like. In addition to the effects of exposure to traumatic stress on emergency services personnel, most groups experience and react to routine stressors such as paperwork, media attention, insufficient equipment, and departmental politics. It is not yet definitively known what the relative impact of these two types of stressors may be on an individual's functioning on the job, but accumulating evidence suggests that both types of stressors are implicated in deleterious effects on psychological adjustment and biological processes.

Recognition of the Problem

The introduction in 1980 of posttraumatic stress disorder (PTSD) into the psychiatric nomenclature via the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (3rd edn.) codified scattered knowledge about the effects of exposure to traumatic stressors from studies of combat veterans from World War I, II, Korea, and Vietnam; women who had been sexually assaulted; victims of the Holocaust; and children who had been sexually molested or physically abused. This codification gave structure to the investigation of the effects of traumatic stress on those who are exposed to such events, either accidentally or by

design. Traumatic stress can be defined as an event or series of events that threaten life, injury, safety, or bodily integrity. The event typically results in the experience of fear, horror, or a similar emotional response in those initially exposed. Obviously, one important difference between emergency service personnel and ordinary citizens is that, over the course of their careers, emergency services personnel are exposed repeatedly to such events. Consequently, these groups have become of considerable interest in the attempt to understand the effects of traumatic stressors on functioning.

The sequelae of exposure to a traumatic stressor varies enormously, all the way from no discernible effect to severe and disabling psychiatric symptoms. The formal psychiatric diagnoses that can result are acute stress disorder and PTSD. Acute stress disorder is diagnosed after exposure to a traumatic stressor when the individual has, within a month of exposure, a sufficient number of four types of symptoms that cause significant disruption in ongoing daily functioning: (1) dissociative symptoms such as depersonalization or derealization; (2) intrusive or reexperiencing symptoms such as nightmares or intrusive mental images of the event; (3) avoidance symptoms such as shunning talking about the event or any reminder of it; and (4) anxiety or arousal symptoms such as poor sleep, irritability, or exaggerated startle response. Acute stress disorder appears to be quite rare in emergency services workers because screening selects out those with obvious vulnerability and training familiarizes and acclimates workers and by so doing is thought to reduce the shocking nature of the events.

When there is the presence of a formal psychiatric disorder, it is more commonly PTSD. PTSD is diagnosed only after at least 1 month has passed since the traumatic event and is characterized by symptoms of three types: (1) intrusion or reexperiencing, (2) avoidance and numbing, and (3) increased arousal. The types of symptoms involved are very similar to those of acute stress disorder, with the exception of dissociative symptoms; these do not need to be present to diagnose PTSD.

It was only after PTSD appeared in the nomenclature that researchers began to systematically study the effects of their occupation on emergency services personnel from the perspective of traumatic stress. There is now a relative consensus that some percentage of workers in these occupations develop psychological symptoms, sometimes to a disabling degree, as a result of their exposure to some of the horrific and repeated incidents with which they are faced. Disasters and catastrophes since the year 2000 have also helped bring these issues to greater

public awareness. Concomitantly, there is a greater recognition that the normal course of reaction to traumatic stressors involves many of the same psychological and biological systems that are implicated in PTSD symptoms.

There have now been studies of police and firefighters in the United States, the United Kingdom, the Netherlands, Australia, and New Zealand, to name a few. The results of these studies are in agreement that PTSD symptoms are present in a subset of employees. They are in less agreement about whether the severity of symptoms warrants a diagnosis of full PTSD or whether partial or subclinical PTSD is more common. As well, there is a wide range of results for the percentage of workers who do meet criteria for a diagnosis. These range from rates of approximately 30% to less than 5%. The high end of these rates are higher by tenfold than the findings of the National Comorbidity Study Replication, a national prevalence study in the United States of ordinary citizens. The 12-month prevalence of PTSD was 3.5%. The severity of symptoms was roughly one-third each for serious, moderate, and mild.

Part of the heterogeneity of the results may be due to the issue of how much time has elapsed since the traumatic event that serves as the trigger for the diagnosis to be made because the natural course of reactions is for a considerable diminution of symptoms over a period of 6 months to 1 year. Another factor may be that some studies have assessed symptoms in relation to exposure to critical incidents on the job without requiring the specification of a distinct event, especially when an event is prolonged in time (e.g., rescue workers at the September 11 site).

PTSD symptoms, whether at the level of formal diagnosis or only of partial or subclinical proportions, are problematic because they interfere with functioning. Moreover, some attempts to deal with the symptoms can be harmful (e.g., the excessive use of alcohol) and exacerbate the symptoms or cause additional difficulties. In the last 5–10 years, awareness and education have helped reduce the stigma associated with sustaining psychological injuries from exposure to traumatic stress, but the attitude that the symptoms are a sign of weakness continues to be relatively prevalent. Those who are affected are frequently not met with compassion or understanding for incurring these difficulties. Consequently, the minimization or concealment of problems from others, and perhaps even from oneself, can lead to not getting help. This tendency may also partially contribute to the wide range of estimates of the degree of symptoms.

Another problem for emergency services personnel is the impact on family members when the worker

does not want to burden his or her loved ones with the stories of difficult or horrific outcomes. Although understandable, not doing so can eliminate one of the most powerful antidotes that helps overcome traumatic stress – social support, a result now documented in two recent meta-analytic studies.

Better documented has been the effect of nontraumatic stressors on first-responders. Stressors such as relations with the media, bureaucratic or political issues within organizations, interactions with supervisors or superiors, and inadequate equipment or backup do not customarily produce intrusion, avoidance, and hyperarousal but, instead, have been shown to be related to more general psychiatric symptoms such as anxiety, depression, and hostility. As well, there are studies that have documented a relationship between hostility and cardiovascular disease, a relationship that has repeatedly been found in ordinary citizens. Unknown at this time is whether there is a synergistic or interactive effect of exposure to both kinds of stressors that is greater than would be expected from the effects of each alone. This area remains ripe for investigation.

Predictors

There has been a growing body of recent work on the predictors of whether a person will have difficulty after exposure to traumatic stress. Because many workers are exposed and only a minority ever develop significant problems, research has focused on identifying factors that might explain why some develop problems whereas others do not. The bulk of the findings come from retrospective studies, with their inherent weaknesses, and have involved mostly men. Gender has been found in some studies to moderate relationships, but the main effect is the well-known result that women report more symptoms. Longitudinal prospective studies of police and firefighters are currently underway, some large scale, but the results of such work has yet to be reported.

From retrospective work, one clear factor that appears to be related to an individual's developing problems is the level of exposure to a critical incident, although the relationship is not as strong as might be assumed. For example, all other things being equal, a police officer who is shot at several times is more at risk than one who is assaulted by a suspect without a weapon. Similarly a firefighter who narrowly escapes a flash-over is at greater risk than a colleague who is just missed by a falling beam. The level of exposure as a predictor has been found in other groups as well (e.g., combat veterans and rape victims). Across all groups, the two meta-analyses found that life threat produced an average weighted effect of $r = 0.26$ and

$r = 0.23$. Some studies, however, have shown that the individual's appraisal of how serious an event was, as opposed to the broad consensus of different levels of threat, is also a factor in determining who develops PTSD symptoms.

A more psychological factor that has been identified is peritraumatic dissociation. Peritraumatic dissociation is the experience of altered time sense, altered sense of self, altered sense of place, disorientation, and panic during and/or immediately following exposure to a traumatic stressor. In a number of retrospective studies of emergency services personnel involved in a large natural disaster, those with the highest levels of symptoms were those who also described having dissociative experiences during or immediately after the trauma. In a group of civilians, a prospective study confirmed the importance of peritraumatic dissociation. The meta-analysis that examined it found that peritraumatic dissociation was the strongest identified predictor of PTSD, with an average weighted effect size of $r = 0.35$.

Preexisting psychiatric difficulties or a family history of psychiatric disorder shows some ability to predict symptomatic level, but the degree is less than more proximal factors. The meta-analyses showed an average weighted effect size of $r = 0.17$ and $r = 0.12$ for prior trauma, $r = 0.17$ and $r = 0.11$ for prior adjustment, and $r = 0.17$ and $r = 0.13$ for family history of psychopathology.

A recent 2-year prospective study of firefighters identified high hostility and low self-efficacy as predictive of PTSD and general psychiatric symptom development. Other studies have shown that cumulative exposure to critical incidents over a career is not as salient a factor as might have been expected.

Biological Factors

In the last 5 years, there has been a marked increase in attention to biological factors in stress response, with a special growth of work in the consequences of traumatic stress on the brain and neuroendocrine systems. Earlier work had established that sleep was disturbed in those exposed to traumatic stressors, but recent findings have differentiated these observations. At least one large-scale study has suggested that in police officers lifetime cumulative exposure to critical incidents was clearly related to the frequency of nightmares but less strongly related to sleep quality. The main factor affecting sleep quality (other than shift-work issues) was the more common stress from the work-environment problems described previously. Studies in the sleep laboratory have tended to confirm that those with PTSD do have diminished sleep quality, but it remains an open question as to whether

general stressors or traumatic stressors exert a larger effect on sleep quality in first-responder groups.

The first biological area examined in the study of the effects of exposure to traumatic stress in emergency services personnel, as well as in research in PTSD more broadly, was the response of the hypothalamic-pituitary-adrenal (HPA) axis to stressors. The role of the hormone cortisol has long been known to be involved in the stress response. Advances in the ease of measurement of cortisol and accumulating findings from many groups exposed to traumatic stress, including emergency services personnel, have shown abnormalities. The most well-established finding is a lowered baseline cortisol on awakening and higher PTSD symptoms. Another fairly well-established finding is relatively more suppression of cortisol following the administration of the synthetic hormone dexamethasone, a finding indicating increased feedback sensitivity. At this point, findings involving the HPA axis are rapidly accumulating, and more careful studies are showing more differentiated results.

A second area of work has been in the area of brain imaging: magnetic resonance imaging (MRI), functional MRI, and positron emission computed tomography (PET). An initial set of findings in combat veterans and victims of sexual assault began to appear in the last decade and tended to show that the volume of the hippocampus was reduced in those who had developed PTSD compared to those various controls. Because the hippocampus is part of the limbic system and is implicated in the formation, storage, and processing of memory, these initial findings were theoretically interesting (recall that intrusive memories of the traumatic event are a unique symptomatic feature). Subsequent studies tended to find reduced volume, sometimes on both sides and sometimes on only the left or right side of the brain, but several found no volume reduction. These ensuing studies were helpful in illuminating the complexity of these brain changes. Currently, it appears that reduction is more common than not and that this is true in police samples as well, but whether smaller volume is a result of traumatic exposure or a risk factor for it is unclear. Newer studies are examining the functioning of the amygdala, which is known to be activated by fear and stress, and the prefrontal cortex, a brain area that plays a role in inhibiting the activity of the amygdala and is involved with complex emotional and cognitive functioning.

Interventions

Given the increased recognition of the psychological consequences of exposure to traumatic stress, many

agencies have instituted programs for debriefing their personnel soon after traumatic exposure. Debriefing as a term is now used in a variety of ways, although its origin is military and was directed at clarifying actual events and improving operations rather than assisting with psychological reactions. Debriefing is now used to refer to some kind of structured intervention designed to assist in the psychological processing of a traumatic event and/or to serve as a preventive intervention. Consumers of debriefings have been extended from those who respond to an event to individuals who can be described as victims or witnesses of the event.

The advent of an evidence base to justify the provision of interventions, most commonly referred to as evidence-based medicine, has had an impact on interventions after traumatic stressors. The practice of evidence-based interventions is predicated on combining clinical judgment with knowledge of external evidence from rigorous systematic research. Several recent summaries of the effects of debriefing for victims have shown equivocal results, with one or two studies concluding that there may even be deleterious effects. These summaries have had a profound impact on the conclusions of the scientific community about the use of debriefing, even though the main summary was based on only nine studies. One fairly recent study of interventions in the workplace after September 11 showed positive effects up to 2 years after the collapse of the World Trade Center towers.

Whether intentionally or due to lack of knowledge, the literature as of this writing has taken the cautions against the efficacy of debriefing based on studies of single-session individual interventions for victims as applying to single-session group interventions for first-responders. This has led to some confusion and a debate about how to help emergency personnel deal with exposure to traumatic stressors.

The most widely used approach in emergency services personnel is critical incident stress debriefing (CISD). This intervention, developed by Mitchell, was developed specifically for emergency services personnel. It, or variations of it made by individual organizations, is still currently widely used and is typically evaluated as helpful and useful, but studies of its actual efficacy have been sorely lacking. Only a single controlled randomized study could be located, albeit with a positive result. It typically comprises seven stages: introduction, facts, thoughts and impressions, emotional reactions, normalization, planning for the future, and disengagement. Widely overlooked in the debate, however, is that CISD was designed as one element of a larger critical incident stress management (CISM) system that includes

precrisis preparation, demobilization and briefings, defusing, CISM, individual crisis intervention, family crisis intervention and organizational consultation, follow-up and referral for assessment, and, if needed, treatment.

Evaluating CISM from an evidence-based perspective is daunting, and it is unclear how many first-responder organizations use the whole CISM approach as opposed to the CISM component only. Given the lack of systematic evidence of efficacy, the persistence of CISM or modifications of it need to be explained. One possibility is that debriefing serves a needed function even if eventually it is shown not to reduce psychological symptoms more than not being debriefed.

Debriefing acknowledges in an organizational framework that reactions to traumatic stress are part of the hazards of the occupation, in the same way that dosimeters symbolize the hazards of exposure to radiation for those who work in such an environment. Unlike radiation, however, whose effects are understood to be out of the control of the individuals exposed, the effects of traumatic stress are often viewed as being under the control of those exposed. Debriefing explicitly acknowledges that this is only partly so.

The goals of psychological debriefing include a decrease of overwhelming emotions and cognitive disorganization and an increase in self-efficacy through the process of giving meaning to the traumatic event and legitimizing emotional reactions. An important component of debriefing is emotional disclosure, something that involves risk for those who see themselves or who think they are seen as people who do not react emotionally. Notwithstanding this view, which is consistent with either avoidance and denial or appropriate positive coping, the very essence of social interaction revolves around telling about what has happened, telling one's story. A debriefing is a formal opportunity to tell one's story and to tell it in a way that brings out aspects that might otherwise be overlooked or ignored, such as having been afraid, ashamed, fearful, confused, overwhelmed, distraught, anxious, revolted, enraged, or any one of many other emotions that arise during emergencies. Even for those who do not volunteer much personal information, information about the natural process of responding to traumatic stress and adaptive coping strategies is often presented.

For the small percentage of first-responders who do develop PTSD and could benefit from professional intervention, the evidence base is more substantial. Antidepressant medications from the broad class of selective serotonin reuptake inhibitors (SSRIs) have

established efficacy and in the United States sertraline and paroxetine have been approved by the Food and Drug Administration (FDA). There is less evidence for the efficacy of other agents (e.g., anticonvulsants or tricyclic antidepressants), and the literature suggests their use is more limited. Both U.S. and UK treatment guidelines endorse an SSRI as the medication of choice.

There is good evidence that trauma-focused psychotherapeutic approaches are also effective. The largest body of evidence supports cognitive behavioral psychotherapeutic approaches, with or without some explicit prolonged exposure. In the largest study of group therapy for veterans with chronic PTSD, exposure therapy was not found to be distinctly superior to a present-centered group that did not focus on the trauma.

There is considerably less work on treatment explicitly for first-responders. Part of the explanation for this is that many individuals seek treatment privately, outside their organization or agency, to avoid the potential stigma or impact on career advancement. Concerted efforts to reconceptualize symptoms that result from exposure to traumatic stressors as psychological injuries, akin to symptoms of physical injury, may go a long way toward mitigating the stigma associated with such responses.

Emotion and Inhibition

Domains of Emotional Inhibition

Pathways from Emotional Inhibition to Health Disorders and Illness Behaviors

Rituals and Therapeutic Interventions

Glossary

Alexithymia

A constellation of cognitive and affective characteristics including difficulty identifying and communicating subjective feelings, a restricted imaginative life, and a concrete and reality-oriented style of thinking.

Behavioral inhibition

A concept encompassing several behaviors in about 15% of otherwise healthy children in response to unfamiliar social events, including reduced spontaneity, subdued emotional expressiveness, shyness, social avoidance and several peripheral physiological hyperactivities. It is thought to be related to limbic-hypothalamic arousal, in response to socially stressful events.

Emotional intelligence

The ability of an individual to adaptively and effectively regulate his or her emotional behavior in a social context. This encompasses the ability to recognize subjective feelings, to manage emotions, to transform emotions into expressiveness and action, to react empathetically, and to shape relationships.

Myogenic pain

Pain stemming from dysfunctional muscular activity as part of motor behavior in relation to stress, posture, movement, and emotion (e.g., low back pain, tension type headache, repetitive strain injury, and myofascial pain disorder).

Socialization

The process by which an individual gradually becomes integrated into the norm and value system of a social group or a society. It is based on the assumption of interaction between the biological organism and the social environment during psychological development.

Torture

One of the most severe stressors motivated mainly by political ideologies and perpetrated in about 60 states worldwide. The adverse effects of torture stem from the man made nature of these stressors and induce specific and nonspecific physical and mental disorders of long duration because they shatter victims' basic assumptions about human benevolence.

Emotion and Inhibition

Emotions are essentially transactions between individuals and their social environment. They give personal meaning to external and internal stimuli and communicate meaning from the individual to others. Emotions are composed of interpretations of intero- and exteroceptive stimuli, intentions, physiological patterns of arousal, and motor behavior including overt emotional expressiveness. The interaction of these different components in the individual and the social and physical environment are mediated by the central nervous system. From a system regulation point of view, emotional expressiveness has two important functions: first, it serves a communicative function in that it facilitates the regulation of person–environment transactions and, second, the feedback function of behavioral expressions controls

the intraindividual regulation of emotion. This means that active responding toward the environmental trigger may influence an experience indirectly through the attenuation of a negative emotional stimulus or directly through self-regulation. Thus, expressive behavior can serve simultaneously as a component of emotional processes and as a coping response. Three prominent scientists of the turn of the century, all of whom were active at a time of major discoveries in neurophysiology, contributed to important developments in the concept of inhibition. The neurophysiology of C. S. Sherrington (born 1857), the theory of the higher nervous system of I. P. Pavlov (born 1849), and the psychoanalysis of S. Freud (born 1856) transformed the principle of inhibition into a key concept in neurophysiology (in the case of Sherrington) and higher mental functioning (in the cases of Pavlov and Freud).

For many years, an inverse relationship between expressive behavior and autonomic responsivity has been documented, such that the inhibition of overt emotional expressiveness can lead to an autonomic overreaction. This has been considered to be a significant factor in the etiology and maintenance of psychosomatic disorders. A number of early researchers in the first two decades of the century reported measurements of high physiological activity in subjects suppressing emotional expression. These studies led toward the concept of internalization and externalization, wherein two behavioral coping styles for dealing with psychological tension were discerned: behaviorally, outwardly directed, or physiologically, within the individual. Following this concept, the term *internalizer* has been used to describe a person exhibiting a low level of overt expressiveness under stress yet a high level of physiological excitation, whereas an *externalizer* is characterized by high expressiveness and a low level of physiological expressiveness in social situations. Temoshok proposed a model of internalizing and externalizing coping styles integrating the severity of stressors which intended to predict the occurrence of mental disorders (dependent on degree of externalizing coping) and somatic disorders (dependent on degree of internalizing coping). Another inhibition theory, put forward by Pennebaker, summarizes the process by which failure to confront traumatic events results in poorer health. The principal assumption of this theory is that inhibiting ongoing behavior, thoughts, and feelings requires physiological work. It has been suggested that the increased autonomic responses of internalizers may reflect the work of behavioral inhibition. Over time, the work of inhibition acts as a low-level cumulative stressor. As with all cumulative stressors, sustained inhibition is linked to increases in stress-related diseases and various other disorders

such as cardiovascular and skin disorders, asthma, cancer, and also pain.

Domains of Emotional Inhibition

A model (see [Figure 1](#)) of how emotional stress, under a given social situation, can trigger or modulate health disorders is described later. Health disorders and illness behavior are considered as different, but related, processes, and distinct mechanisms may contribute dependently and independently to different aspects of a given disorder and its behavioral consequences.

On a phenomenological level, emotional stress can occur on a severity dimension ranging from daily stressors, through more traumatic life events, to more chronic or severe psychotrauma. A common underlying factor among such situations is that each needs to be coped with by the individual. Emotional stress can be seen as being processed by way of an inhibition-implosion dimension (to implode means to collapse or cause to collapse inward in a violent manner as a result of external pressure), modulated by dispositional factors (innate, personality, and socialization).

Innate and socialization factors are of particular importance. Possible individual differences in limbic mechanisms for opioidergic pathways corresponding with increased vulnerability to stress induction have been suggested. Emotional processing relating to the inhibition-implosion idea has been discussed in relation to several topics like control, suppression, type C personality, repression, alexithymia, or ambivalence. Each of these concepts covers different aspects of overt emotional expressiveness from a personality or coping perspective.

Inhibition is the most general term for the incomplete processing of emotional stress when these stressors induce bodily changes (physiological, endocrinological, or immunological) and the cognitive, emotional, and behavioral processing are dysfunctional such that subjective experience and spontaneous expression of emotions and action tendencies are separately or simultaneously attenuated and intra- and interpersonal regulation is disturbed. This process may be a product of innate and/or acquired behavior.

A classification of involved mechanisms differentiates among the following: genetic inhibition, repressive inhibition, suppressive inhibition, and deceptive inhibition. All four classes of inhibition occur in every state of psychophysiological arousal produced by emotional stimulation.

Genetic inhibition reflects the genetically determined basis of behavioral inhibition. Studies working with young children have classified those children

Figure 1 Psychological pathway model of emotional inhibition with neurobiological, social-behavioral, and cognitive pathways between stress/disposition, emotional processing, and subsequent health disorders or illness behaviors (adapted from Traue, 1998).

who were least able to initiate interaction in a social situation with other children and adults as behaviorally inhibited. Most children's degree of behavioral inhibition has been shown to be stable over a period of 5 years. In inhibited children, increased levels of arousal, norepinephrine and salivary cortisol have been found.

Repressive inhibition is defined as emotional processing with attenuated subjective experience of emotional arousal. Emotional expressive responses in repressive inhibition can be based solely on cognitive interpretation of the situation and are nonspontaneously organized. Because the individual is unable to feel his or her own arousal, insufficient response information is experienced, which in turn decreases the need to express emotions or cope with an emotional stressor. In addition, the cognitive interpretation of the situation without the emotional component may

be wrong or misleading. Prolonged bodily arousal and impaired coping could result. Repressive coping style is the best known model for repressive inhibition.

Suppressive inhibition is best circumscribed by suppression of emotional arousal. The emotional arousal is recognized by the individual but spontaneous expressive and cognitive behaviors are involuntarily suppressed. Suppressive inhibition of emotions could result from interactions between innate factors and socialization. For example if individuals show increased responses under stressful encounters, they are prone to socialization conditions of punishment and negative reinforcement, initiating a learning history with decreases in spontaneous expressiveness and increases in bodily reactivity.

Finally, individuals under emotional stress, aware of their bodily reactions and their urge for expressiveness, can voluntarily suppress this need or try to

present a false response to a receiver, called deceptive inhibition. Whether an individual is poker faced or displays a false emotional response, such inhibition consumes cognitive capacity, reducing the individual's coping capacity and providing additional stress.

In reviewing the psychophysiological and psychosomatic data, one is led to the conclusion that emotional inhibition is potentially harmful. However, it should be noted that although the correlations between bodily processes and the above four forms of inhibition support such a notion, in certain circumstances inhibition can be beneficial for the individual and his/her relationship with the social environment. Inhibition becomes toxic when it is related first to physiological, endocrinological hyperarousal or immunological dysfunction, second to longstanding dysregulation of emotions within the individual on a cognitive and behavioral basis, and third if inhibition disturbs the individual's social relations.

Inhibition constitutes a risk factor for health under normal stressors. If the severity of stressors is dramatically high, the mental and physical health consequences are inevitable. In traumatic stress situations like rape, criminal bodily attacks, or torture, the individual may well lose control over strong emotional responses. The emotional responses of horror, panic, and loss of control, could literally cause a violent breakdown in the mental and bodily systems. Such an emotional implosion is visible in the symptom pattern of posttraumatic stress disorder (PTSD): cognitive and behavioral avoidance of trauma stimuli, numbing of general and emotional responsiveness (emotional anesthesia), detachment from other people, and persistent symptoms of arousal such as disturbed sleep, exaggerated startle response, and somatic complaints. In addition, persons with PTSD suffer an increased risk of social phobia and major depressive and somatizing disorders.

The psychological, physical, and social symptoms in PTSD are a form of emotional processing that describes an extreme form of inhibition. While inhibition generally develops over a long time span through interaction between innate and socialization factors, implosion can occur in a very short time as a result of a single event.

Pathways from Emotional Inhibition to Health Disorders and Illness Behaviors

Emotional stress modulated through innate, personality, and socialization factors can trigger, maintain, or worsen health disorders and related illness behavior through neurobiological, social-behavioral, and cognitive pathways. With respect to illness behaviors,

the pathways include biases in symptom reporting, secondary gain by presented symptoms, subjective feeling of being impaired, pressure to seek medical help, and social isolation.

Neurobiological Pathways

It can be assumed that emotional inhibition is strongly neurobiologically based. The behavioral inhibition system and the behavioral activation system have been discussed as possible neurobiological structures. Empirical evidence from between-subject studies shows that inhibited, repressed, or suppressed emotional expressiveness is linked to greater autonomic arousal, both under conditions of emotion induction and voluntary deception. There is rich empirical evidence for neurobiological correlates of inhibition in respiratory, cardiovascular, muscular, digestive, endocrine, and immune functions. Immune functioning is of particular interest because it is the immune system that may be relevant in all sorts of infectious, allergic, and neoplastic illness processes. Inhibited style of processing upsetting events can compromise immune functions, resulting in higher serum antibody titers, decreased monocyte counts, and poorer natural killer cell activity. Other areas of research relevant to the neurobiological pathways of inhibition include hypothalamic-limbic overactivation, prolonged activation of physiological response specificity, hemispheric brain lateralization of emotion processing and faulty interhemispheric communication, the neuroregulation of action, and the behavioral activation and behavioral inhibition systems.

Social-Behavioral Pathways

A variety of social-behavioral pathways connect inhibition-implosion to health disorders and illness behaviors. First, neurobiologically innate factors (shyness, behavioral inhibition, hypersensitivity, introversion) are superimposed by classical and operant conditioning in the socialization of an individual. Since individuals with these characteristics in early childhood are more easily conditioned, the process of socialization involves greater vulnerability to them than it does for others. Under critical developmental conditions, the gap between emotional expressiveness and physiological hyperactivity may increase. A lack or deficit in emotional expressiveness will hinder interpersonal communication. It is implied that deficits in interpersonal communication disturb the development of emotional competence which is important for sharing experiences, maintaining psychological and physical contact, and adapting to the social environment. These are the deficiencies in healthy coping competencies that Salovey and

Mayer termed emotional intelligence. Other consequences of inhibited emotional expressiveness are disturbed social relations resulting in social isolation and a disrupted social support network.

Normally, persons respond to emotion-evoking stimuli with emotional expression, and such reactive expression is realized through facial muscle activity and movements with reafferent neuronal signals in the central nervous system, which contribute to the individual's emotional experience. However, subjective emotional experience does not depend mainly on this nervous input as argued in the facial feedback hypotheses, but feedback does contribute positively to sensitivity toward the physiological aspects of emotion. If this sensitivity is disrupted, an individual will not perceive adequately increased muscle tension or other autonomic nervous system reactions caused by stress and consequently will not initiate healthy relaxing behavior. Bischoff *et al.* demonstrated that the hypothesis of deficient perception of muscle tension holds for myogenic pain. Patients with this kind of pain were reliably less able to judge the extent of their muscle tension than were controls.

It is conceivable that, under unfavorable circumstances, expressive behavior of mainly negative emotions like anger and aggressiveness is punished socially and thus justifiably avoided. The suppression of expressive behavior can be realized by an additional increase in muscle activity. Such avoidance behavior or inhibition is very adaptable in the short term, and it helps to modify a socially stressful situation. This reduction of emotional expressiveness is conditioned by the learning mechanism of negative reinforcement (the avoidance of punishment).

Cognitive Pathways

Memories and thoughts of emotional stressors are generally unpleasant. Increasing severity of the stressful encounter makes imagining the event painful or even unbearable in the case of traumatic experience. Most individuals attempt to suppress or inhibit the thoughts surrounding the events. As soon as the inhibition work begins, the urge to distract oneself and the mental energy put into this process fuels the images. Consequently, triggered intrusions and unwanted thoughts make life more stressful than before. In addition, thought control interferes with natural ways of coping (e.g., sharing the experience with important others and thinking through the event). Therefore inhibition may be dangerous because it hampers the individual who has suffered a critical life event from resolving the stressful experience cognitively and behaviorally.

Other facets of problematic cognitive processing include an alexithymic or low-level thinking style.

As part of the inhibition process, individuals may tend to exclude the emotional content of the stressful encounter from their language representation of the event. Although this may help to avoid negative emotionality in the short term, it impairs one's own complete processing and integration of the stressful experience. The lack of integration into the self-concept makes an individual prone to activation of fear networks. Finally, impaired or unfinished cognitive processing makes an individual prone to a misinterpretation of bodily symptoms. Instead of understanding bodily reactions as part of emotional responses, the individual conceptualizes the bodily reactions as symptom patterns and seeks medical help for illnesses. Badly advised medical treatment procedures result in iatrogenic diseases, trapping the individual in a vicious cycle. Cognitive appraisal of a situation depends partly on facial feedback as a source of emotional information. When the expressive components of emotional reactions are systematically repressed by inhibition, the individual unlearns accurate assessment of stressful circumstances. This learning mechanism occurs since the estimated load of a stress situation is dependent not only on external features of the situation, but also on the subjective experience of stress-conditioned reactions. When, however, an inhibited person takes bodily reactions into account in the evaluation of a situation, his or her judgment will be impaired when the original physiological components of mainly negative emotions are interpreted as symptoms.

In clinical studies, psychosomatic patients (e.g., suffering headache) have been found to report significantly lower stress levels than control groups, but showed nearly twice as much neck muscle tension as the controls. Although the arousal and muscle tension data indicated higher levels of stress, patients were unable or not willing to report those stressors. It appears that patients tend to interpret their stressors in terms of bodily symptoms rather than as underlying levels of stress.

Rituals and Therapeutic Interventions

There is at least some implicit knowledge in most societies that emotional inhibition has negative health implications. The conflicts resulting from the need for emotional regulation on the one hand and the need for disclosure, sharing, and catharsis on the other lead to a variety of cultural phenomena to overcome these adverse consequences. These include older universal cultural rituals (such as rituals of grief or lament) or religious acts such as confessions. The Western (Wailing) Wall in Jerusalem, where Jews have been going for centuries to deliver a written

prayer, is possibly an example of an ancient disclosure phenomenon. Today people can deliver their prayer to the Western Wall via the Internet, and similar services are offered in connection to Christian confession. Contemporary western societies have also introduced psychotherapy for enhancing emotional expressiveness. Here, talking or writing about emotions is encouraged as well as acting out emotions, in role plays. Assertiveness training aims at effective expression of emotion, and catharsis-based techniques like confrontation are modern remedies for anxiety, posttraumatic stress disorders, and the like. All of these techniques seem to have in common that they are directed at the construction of meaning from emotional experience. Different cultures tend to construe emotional experience (including stress) in different ways, such that many non-Western cultures tend to emphasize the somatic components of emotional suffering, whereas Western cultures focus on the psychological components. Such cultural differences could influence the pathways between emotional inhibition and illness. Hence, clinicians should take into account the relevant cultural conceptions of emotional experience and behavior a client has been exposed to when choosing interventions for emotional inhibition. If a client emphasizes the somatic components of his or her reaction to a very stressful event, it may not be (dysfunctional) emotional inhibition, but rather a cultural construal of emotional suffering. Only when culture-sensitive exploration reveals lack of insight into relevant psychosocial factors should the possibility of dysfunctional emotion processing be considered.

Glossary

Autonomic nervous system The nervous system, consisting of three branches, two of which, the sympathetic (energy mobilizing) and parasympathetic (energy restorative), play a critical role in the stress response. Sympathetic effects are widespread; parasympathetic effects are localized to particular organs. The third branch, the enteric system is localized in the gastrointestinal tract and affects the gut during stress.

Conspecifics The members of one's own species. Much emotional behavior has evolved in interaction with members of one's own species and is designed, therefore, for regulating behavior within the social group.

Cortisol A hormone produced by the outer layer of cells (cortex) of the adrenal glands. Its multiple functions include the conversion of fats and proteins to sugars usable for energy expenditure, and moderating the immune response. Secreted as part of the hypothalamic-pituitary-adrenocortical stress response.

Cytokines Protein molecules formed by immune cells that communicate with and activate other subsets of immune cells and have direct effects on the central nervous system, producing sickness behaviors, including fatigue, malaise, and anhedonia.

Dopamine A neurotransmitter important for addictions and the activation of physical movement. Severe deficits lead to physical freezing (Parkinson's disease) and are

Epinephrine

Emotion circumplex

Hierarchical mechanisms

Insulin

Moods

Primary emotions

Schemata

treated with dopamine replacement therapy (L-Dopa).

A hormone that has widespread effects throughout the body. It is produced by the inner part of the adrenal gland (medulla) and plays a major role in the stress response, increasing heart rate and blood pressure, activating motor activity, releasing sugars for work, and stimulating immune responses. It is the end product in the sympathetic-adrenal-medullary stress response; also known as adrenaline. A circular representation of affective space defined by two dimensions: pleasant (love; mirth; happiness) to unpleasant (anger; determination) emotions and activated (surprise; suffering; fear) to relaxed (contempt; disgust) emotions. The names of the dimensions and specific emotion terms vary slightly from study to study.

Psychological and physiological processes described in terms of a hierarchy of behavioral control mechanisms. The output of each level produces reactions that affect activity at both lower (automatic action) and higher (conscious thought) levels.

A hormone found in various forms in plants, bacteria, and invertebrate and vertebrate animals; in humans it is formed in the pancreas. It is critical for the conversion (and hence the storage) of sugars as fats. Insulin deficits lead to excess blood sugar, called type 1 diabetes in children (caused by destruction of insulin-producing cells) and type 2 in adults (typically caused by excess weight), which can result in destruction of small blood vessels and lead to blindness, loss of limbs, kidney damage, and heart disease.

Affective states that vary in quality, as do emotions, but describe milder fluctuations in feeling. Moods are typically longer lasting than emotions and are presumed to involve the same underlying psychological and physiological systems. A finite set of six emotional reactions (happiness, surprise, fear, suffering, anger, and disgust) that have been identified in repeated studies and are presumed to be innate and potentially identifiable in people in all cultures at all times.

Organized neural structures formed by associative learning (repeated pairing of stimulus and response) that integrate

stimulus inputs with interpretations (meaning) and motor reactions. Schemata operate automatically, without conscious thought or voluntary effort, creating conscious emotional experience (fear, anger, and joy) and overt responses (flight, fight, and approach).

Self-conscious emotions

Emotions that can appear only after the infant has formed a central neural representation of him- or herself as distinct from other humans.

Subcortical areas

Collections of neural cells or nuclei that are important for emotional behaviors such as fear and positive affect. These nuclei lie deep within the brain and are less accessible and harder to study than the cortex. Ongoing research continually expands our understanding of their function (e.g., the amygdala is involved in learned fear behaviors and fear memory).

Emotional experience and emotional disorders have occupied the minds of philosophers, physicians, and laymen through much of recorded history. Beginning with Plato in the fourth century BC, emotion has been set apart from rational thought and typically viewed as a potential source of danger and dysfunction. In the second century AD, the Greek physician Galen identified four emotional temperaments – sanguine, choleric, melancholic, and phlegmatic – which he linked to four bodily humors or fluids. Historians of the Middle Ages described how moments of rage led kings to slay close friends and grieve them the following day. And since the late nineteenth century, physicians have hypothesized that anger and hostility generated by the stress of competitive, rapidly paced modern life explain the ascendance of cardiovascular disease as a major source of death in industrialized nations. Today, most Westerners believe that emotional distress is a primary cause of diseases ranging from life-threatening cancers and cardiovascular disorders to the annoying common cold.

The prominence of emotion in historical and medical thought and everyday life contrasts with the scanty attention given emotion in psychological research during the first half of the twentieth century. Only in the past 3 decades has emotion emerged as a focus of research in psychology and neuroscience, although the quantity of research on emotion has been dwarfed by the vastly greater number of studies on cognitive processes. It has proved far easier for computers to simulate perception, thought, decision processes, and learning than to describe and make sense of emotions. Disagreements in defining emotion, the subjectivity of human emotion, and unwarranted confusion about the relationship between

psychological and physiological analyses have been responsible for this state of affairs.

The Relationship between Psychological and Physiological Models of Emotion

William James's elegant prose stimulated a massive search for patterns of peripheral autonomic nervous system activity (e.g., heart rate and sweat gland activity) when he argued that the commonsense view that "... we meet a bear, are frightened and run ..." is a sequence that "... is incorrect, that the one mental state (fright) is not immediately induced by the other (seeing the bear), that the bodily manifestations must first be interposed between, and that we feel ... afraid because we tremble ..." (1890/1950: 450, 451). Although the strong form of James's somatopsychic model of affect has not been supported, there is growing knowledge regarding visceral influences whose effects on higher brain processes may be relevant to understanding emotion. Nonetheless, decades of study have failed to generate compelling evidence of clear patterns of autonomic activity associated with specific feelings, due perhaps to a failure to attend to the more complex features of James's writing. One lesson to be taken from this search is that data on physiological activity cannot, by themselves, illuminate our understanding of emotion unless these data are related either to behavioral manifestations of emotion such as overt action or to self-reports of private experience. This is just as true of real-time images of brain activity now available to affective neuroscientists as it was of signs such as perspiration and an irregular heart beat on which the early physicians first based the link between emotion and bodily processes. Psychological analyses of subjective feelings, cognition, and action and physiological analyses of central neural activity and peripheral physiology are parallel descriptions of unfolding emotional events. One description does not substitute or explain the other. A full understanding of ongoing emotional processes requires elaboration of both psychological and physiological models and the analysis of their linkages. Each type of analysis informs, defines problems, and sets limits or constraints for the other.

Two Questions about the Relationship of Emotion and Cognition

Psychologists and neurobiologists, not always in opposition to one another, have taken contrasting positions on the often heatedly debated question: Are emotions independent of cognition? Those arguing no assert that emotions always follow cognitive

appraisals; that is, the bear must be understood as endangering one's life before its presence elicits fear. Those arguing for independence assert that emotions can be provoked without prior thought or reasoning and support their position by pointing out that stimuli processed by subcortical areas of the brain can evoke emotion before these stimuli are enriched by cerebral cognition. The heat of debate is often unaccompanied by light because the advocates of both sides are seldom clear as to the meaning of cognition and the meaning of emotion. If we recognize that we are describing a common process from two separate vantage points, we can decompose the argument into separate questions.

Does Cognition (Elicit) Precede Emotion?

An answer to the timing question depends on the meanings of cognition and emotion. If cognition is defined as complex logical or deliberate reasoning, the answer is: cognition seldom precedes emotion. If cognition includes the automatic, sometimes preconscious representations of a stimulus, the likely answer is: very often. An explosive sound to one's immediate rear or the unexpected sight of a scorpion resting on the bathroom ceiling of one's vacation suite is likely to evoke startle and an abrupt shudder of fear. Being cut off by an aggressive driver can provoke anger, and the sight of one's grandchild emerging from an airliner readily elicits joy. Emotions are often provoked by recognition processes that occur far more swiftly and with less involvement of working memory than that which is needed for abstract logical thought. Different levels of cognition, from minimum perception through recognition to more complex cognition, can be antecedents of emotion, with the quality of the emotion elicited depending on features of the information (surprise, threat, etc.).

If cognition is broadly defined, it is likely that most emotional experiences are preceded and elicited by cognitive activity, a point with which James would agree. But what is usually the case need not always be so. Emotional reactions may also be the direct product of neurochemical changes in the brain and the body. Cytokines produced by the immune system's response to infection act on the nervous system and appear to produce depressed mood, whereas exercise elevates levels of cerebral peptides to create positive mood. Although it is likely that emotional episodes are more frequently initiated either by external events or by images and thoughts about such events rather than by detached neurochemical changes, we ought not regard the sequence as rigid because cognitive and emotional processes interact with one another during ongoing emotional episodes.

Can There Be Emotion without Cognition?

The second emotion-cognition question concerns whether one can have an emotion without cognition. At a time when the literature was nearly entirely devoid of evidence linking specific patterns of peripheral autonomic response to specific subjective emotions, Schachter and Singer hypothesized that emotional behavior and experience require the combination of unpatterned peripheral physiological arousal with the perception of a meaningful contextual-environmental cognition. The perception of unpatterned autonomic activity is necessary for an emotional episode, but the contextual or environmental context defines the meaning of the episode and gives it its particular quality (i.e., fear, anger, or joy). Thus, the scorpion on the bathroom ceiling identifies the perceived physiological activity as fear, the aggressive driver defines it as anger, and the grandchild's smile causes it to be experienced as joy. Advocates of this proposition were not mixing psychological and physiological explanations because their hypothesis proposes that it is the perception of physiological activity that is necessary, but not sufficient, for emotional experience and action.

Schachter and Singer's classic 1962 experiment illustrates the nature of this combinatorial hypothesis. Subjects were recruited for a study of the effects of a pharmacological agent on vision and were told they would have to wait 20 min after an injection of the agent before the visual tests could begin. For some subjects, the injected agent was epinephrine, which activates the autonomic system and provides the somatic arousal hypothesized to be necessary for emotion; other participants were inoculated with an inert placebo. Approximately one-third of the participants given epinephrine were informed about its actual side effects, that they might notice shakiness in their hands, warmth in the face, and heart palpitations. These informed participants had a nonemotional cognition to explain their somatic activation. The other epinephrine-injected participants were either uninformed or misinformed about the somatic effects of the injection. The misinformed group was given to expect somatic cues irrelevant to epinephrine as a control for focusing attention on the body.

The experimenters then added the second cognitive component presumed to be necessary for the experience of emotion; this component was not expected to elicit emotion in the accurately informed or the placebo subjects. The cognition was supplied by a second participant, actually a collaborator of the experimenters, who enacted one of two routines during the 20-min wait before the visual tests were to begin. For some subjects, the collaborator enacted

fun-generating activities such as making and flying paper airplanes; for others, the collaborator enacted anger-generating activities such as expressing irritation with the questionnaires and finally refusing to participate and marching angrily from the room. As expected, the epinephrine uninformed and misinformed subjects emulated the happy or angry actions that supplied a meaning for their somatic arousal. Less emotional behavior was apparent from the participants given a placebo because they lacked the necessary bodily arousal and from the informed epinephrine-injected participants because they were accurately informed and had an explanation for their somatic arousal.

The combination hypothesis has not fared well over time. It faltered for several reasons. First, it could not account for the presence of fear-motivated avoidance seen in many phobic subjects, particularly males, in the absence of strong signs of physiological arousal. Second, later experiments failed to replicate the findings, particularly with regard to anxious emotion as distinct from fear or anger; epinephrine might elicit anxious upset without the need for a cognitive cue. Most important, however, the hypothesis that meaningful cognition was necessary to provide the quality of emotional behavior identified the hypothesis with social constructionist theories, all of which ran afoul of accumulating evidence that a set of discrete or primary emotions are part of our innate constitutional makeup. The Schachter and Singer study does, however, make an important, often ignored, point – under ambiguous conditions, environmental cues play an important role in shaping emotional reactions.

Primary Emotions Theory

Seemingly in sharp opposition to social constructionist positions are theoretical models postulating a set of primary emotions that are universal and inborn. Specific problems with this proposal need to be kept in mind as we review the evidence in its favor: There is disagreement as to which emotions should be included in the set of primaries, and there are various shades of meaning as to what is meant by universal and inborn.

The Primary Emotions

Expressive behavior and primary emotions The use of facial, vocal, and postural expressions as the pathway for the identification and study of emotion was stimulated by Charles Darwin's treatise on *The expression of the emotions in man and animals* (1872). Patterned facial expressions, body postures, and vocal tones were seen as indicators of emotional

states and as ways of communicating emotional states to others and, more important perhaps, as the source of emotional experience in the actor. Thus, in contrast to William James, who emphasized the role of visceral somatic activity as the source of emotional experience, theorists of primary emotions believe that the expressive face and voice tell both others and ourselves what we are feeling.

Early studies of judgments of facial expression conducted through the first half of the twentieth century generated a picture of emotional life with specific emotions such as joy, contentment, anger, fear, and sadness arranged about the circumference of a circular plane defined by two axes: pleasant–unpleasant and active–passive. The circumplex emerged from statistical summaries of the judgments made of photographs of actors posing specific emotions. These enacted expressions (to look happy, contented, angry, fearful, disgusted, sad, etc.) were appropriately classified by judges ranging from newspaper readers who mailed in their ratings of the pictures printed in local newspapers to the more usual undergraduate psychology students. The judgments mirrored what the actors had been instructed to pose and the circular model provided an economical description of the data.

Critics of the primary emotion hypothesis pointed to the lack of agreement among the lists of affects proposed by different theorists. This criticism has been countered, effectively in our view, by identifying primary emotions about which all agree, that is, joy; contentment; sadness or depression, disgust, fear, and anger. Disagreements about these primary emotions have been more apparent than real, reflecting differences in labels used to refer to the same emotion. Disagreement about expressions of surprise and interest are less easily reconciled because they are labeled as emotions by some theorists and not by others.

A second issue regarding the concept of primary emotions concerns the role of facial expressions in subjective emotional experience. Some theorists argue that the subjective experience of the primary emotions is produced by sensory feedback from facial muscles, although there is disagreement as to whether it matters if the expression is spontaneous and genuine as opposed to voluntary and faked. Although it seems reasonable to assume that behavioral activity, including that from the face, can intensify emotional experience, there is reason to doubt that peripheral motor feedback is necessary for subjective emotion.

The primary emotions are universal Although Ekman and Friesen were not the first to examine emotional behaviors cross-culturally, the methods they used in their excellent cross-cultural work on

the judgments of emotional expression provide strong evidence in support of primary emotions. This work was important because it undermined the social constructionist position that cultural factors (i.e., learned behavioral rules and cognition) governed the emergence of all emotional expression and subjective feelings. Rather than asking their participants, New Guinea natives who had no contact with Western culture and Californians who had no contact with New Guinea culture, to provide emotional labels for photographs of facial expressions, participants were asked to judge which of several photographed expressions fit a specific social situation. The New Guinea natives picked the smiling face of a Californian as the face that would resemble that of a valued relative being greeted at the door of their hut, and Californians made similar selections from the photos of New Guinea natives. Expressions were matched to the appropriate situation on both sides of the Pacific. Primary emotions seem to be universal.

Are primary emotions innate? Studies of the emergence of emotion in infants are a second source of evidence in support of the contribution of innate primary emotions. Words must be used with care in discussing infant emotion because we cannot question the 2-h-, 2-week-, or 2-month-old infant about his or her emotional state; indeed, the questions we can ask of the 2-year-old are also limited. We can, however, observe infant expressive behavior and infer emotional experience and emotional states, although with due caution. Studies conducted during the 1930s suggested that infants could display little more than contented smiles and undifferentiated states of distress. The failure to find differentiation appears to have been due to the coarseness of the stimuli used to elicit emotion (e.g., dropping and catching the infant after a 1- to 2-foot free fall). Studies conducted since then made clear that, although expressive behavior in infancy is less differentiated than that in adults, it is not simply a two-dimensional affair, that is, one dimension of sleep-active and another of smiles-distress. Indeed, infants less than 1 week old mimic the facial expressions of adults, such as smiles or looks of surprise or sadness, and respond with angry distress when the delivery of a sweet-tasting liquid is discontinued.

Although the data suggest the presence of innate patterns of facial expression for primary emotions, we can infer, but not prove, that these expressive patterns are associated with subjective feelings. This does not mean, however, that these states and/or their overt motor expressions are free of cognition. Mimicry of facial expressions is dependent on perceptual processes. The infant must perceive critical features of

the face if he or she is to mimic the adult's expression. The angry response to withdrawal of reward is contingent on the infant's acquiring the expectation that his or her sucking response will deliver a sweetened substance; learning is required for there to be a disconfirmed expectation. It is clear that the emotional expressions of infants are embedded in perceptual and cognitive processes, although the cognitive processes surrounding these behaviors are relatively primitive in the earliest days of life. Affects linked to such cognition (e.g., joy, sadness, disgust, anger, and surprise) emerge during the first 6 months of life. The cognitive context for emotional elicitation becomes more complex during the second half of the first year. Among the most interesting of these changes is the emergence of self-conscious emotions following the growth of awareness of an objective sense of self. Lewis and his colleagues have shown that affects such as empathy and envy appear only after the infant clearly recognizes him- or herself as a physical entity. The evidence for self-recognition is the infant's reaching toward a mark drawn on his or her forehead while looking in a mirror. An infant who cannot identify his or her mirror image cannot experience self-conscious emotions; emotional reactions are indeed embedded in cognition.

The Function and Structure of Emotion

Functions of Emotion

Findings showing that primary emotional motor patterns are embedded in perceptual and cognitive processes have important implications for the functions and structure of the psychological system producing emotional behavior. The communicative and motivational properties of emotion are two that stand out.

Emotional communication and social regulation

Darwin suggested that the function of most expressive behavior is to communicate action-readiness to conspecifics. Expressions communicate readiness to fight (anger), to flee (fear), to avoid a harmful substance (disgust), to withdraw (depression), to share pleasure (joy and love), and to take in, imbibe, and/or attend to an event (interest). Emotional communication is the glue that bonds infant to parent, and unchecked infant expressions of distress can ignite abuse. Despite the common view that emotions represent sources of irrationality and dysfunction, other theorists since Darwin also have emphasized the adaptive value and organizing function of emotion.

Ethologists observing animal behavior in the wild and anthropologists and sociologists observing

behavior in humans have identified the many ways in which emotional communication creates in-groups and out-groups, provides internal structure in organizations and face to face groups, and moderates the flow of interpersonal behavior in dyadic interaction. Fear vocalizations in chimpanzees communicate the presence of enemies to other members of the local clan, allowing all to escape predation. Sadness, with its depressive postures and self-abnegating cognition, and fear, with its associated flight, defend against attack from higher-status members of the tribe; aggressive anger establishes who is lord. The importance of emotion in regulating social behaviors is consistent both with the appearance of emotional expression early in infancy and with the intimate connections between expressive responses and cognitive processes. Most of the perceptual events that activate emotional reactions early in life are interpersonal, for example, infant and parental smiles, infant distress signaling parental assistance, and self-awareness as the basis for self-referential emotion. Affectively based commitments to institutions and lifetime partners in later life involve yet more elaborate integrations of multiple primary emotions with complex cognition. Emotional communication therefore requires the integration of affective and cognitive processes.

Emotional motivation Emotions have an energizing or activating role in behavior, and they seem to instigate movement toward or away from environmental stimuli. This function calls on systemwide resources for the support of overt action. Thus, neurotransmitters of the central nervous system that are linked to specific emotions are involved in complex chains of neurochemical activity for marshaling the sugars needed for energy expenditure. Emotions contribute more to motivation, however, than the mere energizing of behavior: They direct attention to specific cues, define particular goals for action (person to attack vs. person with whom to share resources), and shape coping procedures (i.e., thoughts and actions to meet these goals). This emphasizes once again the importance of the network of perceptual, cognitive, and motor processes associated with emotional behaviors.

The Structure of Emotion

A variety of frameworks have been suggested to integrate the array of issues we have covered. Those that seem best able to manage this task postulate a hierarchical mechanism underlying the creation of emotional activity. The primitive, innate primary expressions of emotion that are elicited by specific environmental stimuli form the base of the hierarchy.

The repeated elicitation of these primary emotions connects them with a wider range of eliciting cues (smiles of a particular parent) and with varied responses on the output side (reaching to be held). This history creates schematic structures that enrich the primary affects, connecting them to an increasingly wide range of stimuli and behavioral responses. Because schemata develop prior to the availability of a rich verbal system, much schema development involves nonverbal motor learning and this system remains automatic and subject to limited volitional control. A consequence is that control over emotional behavior is a central problem for managing life's adversities and temptations and is central to contemporary developments in psychotherapy.

Emotional life also becomes increasingly complex and mature through the integration of multiple primary affects in schematic structures. Reflective melancholy, pleasure linked to sadness about a valued but lost past, emerges from combinations of previously separate primary affects and their specific schematic structures. And just as cognitive growth and the awareness of self allow for the onset of emotions of shame and guilt in infancy, affective changes in later life and in response to chronic illness involve major cognitive shifts in the self system and alterations in the biological substrate underlying the primary affects at the base of the emotion hierarchy.

Biology, Emotion, Stress, and Health

Two final points merit brief comment. The first focuses on the nature of the biological systems involved in emotional behavior and the second on connections between emotion and health.

Biological Basis of Emotion

Panksepp marshaled an impressive array of neuroscience data in support of the position that specific neurobiological systems underlie the primary affects; the base for the primary emotions lies deep in the upper portion of the brain, not in the peripheral autonomic system. The chemistries of the body (e.g., epinephrine, dopamine, a vast array of peptides, and notably insulin, cortisol, and other agents involved in the storage and availability of sugars for energy expenditure) affect this central system because the brain and body are in bidirectional communication with one another. It is interesting to note that these chemistries regulate communication and social regulation even in single-cell bacteria. Insulin equivalents that transport sugars into the cell communicate the presence of food to conspecifics and regulate the behavior of the colony. This may be seen as a parallel to the action of the mammalian brain, which facilitates

intraspecies emotional communication by connecting emotional reactions to a broad cognitive base. A bacterium will not release a sufficient amount of this insulin-like factor to capture a nutrient unless other members of its local community also detect the nutrient. Communicating with one another precludes the premature use of this resource in the presence of a limited quantity of nutrient. Although these functions do not depend on the presence of a central nervous system, as in multicellular organisms, the action of such chemical systems may provide insight into the origins and function of complex emotion systems.

The neurobiological substrates for affective processes are currently the subject of intense investigation. Accumulating evidence has informed theory regarding the role of systems involving the prefrontal cortex, hippocampus, and amygdala in generating affective experience, emotional communication, and other behavioral expressions of affect and motivation. This work has also stimulated the rethinking of the distinction between cognition and emotion given that common as well as separate neurobiological structures have been implicated in both functions. In sum, the biological description of the emotion system is being linked to functional analyses in showing that emotions are critical sources of information for the regulation of resources, interpersonal behavior, and survival.

Emotion, Health, and Illness

The virtual elimination of life-threatening respiratory and gastrointestinal infections, the extension of life into the seventh and eighth decades, and the emphasis on autonomy and self-control in industrialized Western nations confront us with the chronic diseases of old age. One result has been the need for effective forms of self-management for prevention and control of chronic conditions and the revival of, it is hoped, life-improving folk medicine. Billions of dollars are spent annually on natural herbal products, mega-vitamins, special diets, stress-control programs, biofeedback, and so forth for the prevention and treatment of disease. The reduction of stress and avoidance of negative affects are culturally accepted, alternative routes for prevention and treatment. With the exceptions perhaps of cardiovascular disease and the common cold, however, there is scant evidence for such a direct, causal role of stress or negative emotion on disease, although the evidence for an indirect role is abundant (e.g., through the motivation of risk behaviors such as cigarette smoking and excessive alcohol consumption). Life-style behaviors related to emotional and motivational processes are critical not only for the prevention of chronic illness but also for their control. For example,

exercise, dietary control, and weight loss are nearly twice as effective as medication for preventing the onset of diabetes among individuals at very high risk. Despite the evidence, many people seem more concerned about reducing stress than quitting smoking, exercising, and reducing saturated fats in the diet, which may be far more likely to reduce the possibility of serious disease.

What lends credence to the commonsense belief that stress causes disease? Clearly stress makes us feel bad and stress reduction makes us feel better. Because physical illness and emotional states are bidirectionally related, fatigued and depressed mood often both precede and follow the onset of clinical illnesses such as the common cold. The immunological responses that defend us against disease have direct effects on the central nervous system; they cause fever and shivering, inhibit motor behavior and eating, and create fatigue and its associated feeling state of depressed mood. Thus, rather than seeing emotional states as directly causing disease, it might be closer to the truth to see emotional states as indicators of active disease processes and of reduced resistance to disease. Just as our thermometers tell us the temperature without causing the weather, so too might emotions indicate that something is amiss without directly causing illness.

Most important, emotions are responsive to a wide range of events. From a psychometric perspective, emotions are poor indicators of disease states; they may be sensitive indicators of illness, but they are nonspecific. Thus, if one is actively connected to one's social world, one will feel emotions of joy and distress, and distress may indicate the presence of chronic, life-threatening illness in elderly spouses, family members, and friends, and not just oneself. Because being connected enhances survival, distress caused by illness in a spouse or family member may be positively associated with function and good health. Because they are nonspecific, measures of emotional traits and states are poor predictors of health-relevant behaviors; for example, generalized anxiety is a poor predictor of management of diabetes complications. Prediction of self-management behaviors improves when affect is assessed in association with specific perceptions; for example, a fear of hypoglycemia predicts poor adherence to the use of insulin and elevated blood glucose, and fear of foot amputation predicts efforts at effective self-management. In short, an examination of the implications of emotion for physical health agrees with functional and neurobiological analyses in pointing to the interaction and integration of emotional process with perception, cognition, and contextualized action.

Concluding Comment

Both psychological and physiological accounts of emotional processes are advancing rapidly, the two types of description complementing one another and deepening our understanding of emotion. Neither alone is sufficient – physiological analysis does not inform us about emotion unless it can be related to a theoretically and empirically clear picture of the behavioral psychology of emotion. As both sides of the emotional equation are extended and elaborated, we can expect to deepen our understanding as to how these processes connect to our ecology, both social and physical, and to our genetic makeup. We hope that such knowledge will make us less susceptible to false nostrums and more accepting of life styles that maximize well-being and that help us to cope with and make use of the angers, fears, and depressions that are intrinsic to life.

History

Rationale

EAPs and Stress

Program Characteristics

Challenges and Future Directions

Glossary

Counseling services

The provision of professional advice and guidance utilizing psychological methods or various techniques of the personal interview to guide an employee in a constructive direction that will lead to the development and realization of the individual's potential.

Employee assistance program (EAP)

Employer-sponsored counseling, educational, and mental health services that are available to all employees on a confidential and self- or supervisory referral basis.

In-house vs. external employee assistance program (EAP)

Services provided by counselors who are employees of the company vs. those provided by an external firm.

Work-family conflict

Incompatibility in some aspects of the simultaneous pressures from the work and family domains that makes it difficult for employees to meet the demands of one or both domains.

Employee assistance and counseling are resources utilized by work organizations to manage employee stress and enhance workplace effectiveness through preventing, identifying, and resolving personal and work-related problems. Employee assistance programs (EAPs), specifically, are employer-sponsored counseling, educational, and mental health services that are available to all employees on a confidential and self- or supervisory referral basis. These programs can offer assessments, referrals, and clinical, preventive, and educational services to employees and their families to aid in managing work and life challenges.

History

EAPs grew out of the 1940s occupational alcoholism prevention programs (OAPs) that focused on alcohol abuse in the workplace. In the 1970s, the scope of services was broadened to include mental health and drug abuse problems (often referred to as broad brush services), hence the development of EAPs. During that time, employers began adopting measures to assess the costs at the individual and organizational level related to alcohol and drug abuse as well as occupational stress and individual and family problems.

In the late 1980s, work organizations also began to consider the overall mental, physical, and emotional well-being of their employees by incorporating preventive mechanisms into the structure of traditional EAPs as well as by developing employee enhancement programs (EEPs). Preventive models focused on stress management and other addictions such as overeating and smoking.

EAPs now tackle employees' work and life challenges and overall well-being involving workplace stress and conflict, relationships and family problems, financial and legal problems, childcare, eldercare, and career counseling. A recent estimate of EAP utilization indicates that more than 80 million individuals within the United States have access to an EAP, an approximate 250% increase from only a decade ago.

Rationale

Recent research reveals that workers' job performance and workplace productivity can be affected by work-related stress, family conflicts, and personal challenges. As an illustration, depression costs \$44 billion annually in lost productivity, and substance abuse and mental illness cost \$100 billion annually, or \$3000 per employee. Hence, employee assistance and counseling provide supports to the employee and the employer, resulting in shared benefits including enhanced employee mental, emotional, and physical well-being, improved job performance, and improved organizational functioning (see [Figure 1](#)). Employees utilize EAPs and equivalent counseling programs as resources for managing work-related or family/personal stress. For the employer, EAPs help (1) contain health-care costs, (2) provide resources that supplement current organizational support services, (3) demonstrate care for their employees and enhance the work organization's image, (4) prevent or contain potential legal problems, and (5) address labor/organization relations.

Figure 1 Value of employee assistance and counseling.

EAPs and Stress

EAPs and Job Stress

Employee assistance and counseling services are available to aid in managing stress that is associated with employees' work and life experiences. Counselors and therapists who provide those services (typically social workers, psychologists, and professional counselors) generally operate under the assumption that stress is not necessarily bad and that some stress is a normal part of work and life, but that excessive stress could be detrimental to both emotional and physical health. As such, employees can experience stress in the workplace in several areas, most notably in areas related to their job role and perception of social exclusion. These forms of work-related stress

can adversely affect worker outcomes, such as lost job productivity, counterproductive work behaviors, and preventable turnover.

EAPs often address stress on the job by offering individual counseling, stress reduction seminars, or counseling management on how to restructure the work environment or work processes to reduce stress. The experience of job stress is the psychological state that represents an imbalance between peoples' perceptions of the demands placed on them and their ability to cope with those demands. Typically, employees experience too much work (role overload), a conflict between their expectations of their jobs and the actual reality of those jobs (role conflict), and lack of clarity regarding their supervisors' or management's expectations from them (role ambiguity).

However, it is not only excessive demands that are the source of job stress but also understimulation, represented by work tasks that are boring, too simple, or not challenging.

Employee assistance services can also offer supportive resources to help employees negotiate perceived stress-related feelings of exclusion within the organization. The inclusion–exclusion continuum reflects the extent to which individuals feel part of important organizational processes that affect their jobs, have access to the organizational decision-making process, and have access to its information networks. Research over the past two decades indicates that exclusion from organizational information networks and from important decision-making processes is a significant problem facing today's diverse workforce. Perceptions of exclusion may play a critical role in explaining the connection between those employees who experience themselves as different from the corporate mainstream and their job stress, well-being, and other worker outcomes (e.g., job satisfaction, productivity, and turnover).

EAPs and Work–Family Life Stress

In the past two decades a new field of workplace service delivery, as well as a new field of scholarly inquiry, have emerged that focus on the stress associated with the need to balance work and family and, more generally, work and personal life. Many workers struggle to negotiate the demands of work with the expectations from their families and life outside of work, which include familial responsibilities such as child care and elder care, activities related to individuals' personal fulfillment, and activities related to community contributions and civic duty. Balancing or integrating the demands of work, family, and life can be associated with specific stress-related outcomes for workers, based on the presence and absence of conflict between their roles. The research on work–family and work–life balance has focused predominantly on the United States and Europe, but in recent years there has been more research on other countries and even some comparative studies that examine the similarity and differences in challenges faced by workers worldwide.

More and more work organizations are introducing work–family or work–life programs as part of, or in addition to, their EAP services. These services focus on the conflicts that employees experience in reconciling their work and family roles. They include individual and family counseling to help employees cope with the stresses associated with, for example, having to care for a sick parent or taking care of a new baby. In addition, work–family or work–life programs include new policies that allow employees to

take periods of paid leave for family or personal reasons. More recently, workplace flexibility options have emerged as a way to address conflicts between work and life outside of work, including flexibility in scheduling full-time hours (e.g., compressed work weeks), flexibility in the number of hours worked (e.g., reduced work hours per week or working part of the year), career flexibility with multiple points of entry, exit, and re-entry into the workforce, and the ability to address unexpected and ongoing personal and family needs.

Program Characteristics

Service Delivery Models

There are several different EAP service delivery models, described in the following sections.

Alcohol and drug abuse prevention and treatment vs. broad brush Alcohol and drug abuse prevention programs focus on providing referrals and counseling for employees who are addressing substance abuse problems that can impact the workplace. Broad brush programs essentially focus on an expansive realm of services that aid employees in managing their marriage and family, emotional, financial, and legal problems.

In-house EAP vs. contracted EAP services Some companies choose to provide EAP services internally, by counselors who are themselves employees of the organization, while other companies choose to contract the services from external EAP providers. The latter are firms that provide the entire EAP staff. The advantages of the in-house service delivery model include the counselors having a greater familiarity with the organization's structure and the ability to provide organizational-level interventions when needed (e.g., when the cause of a problem is at the work unit or department level). The advantages of the external EAPs is that they provide a perceived (though not necessarily real) greater level of confidentiality, and sometimes they are less expensive than the in-house services.

Consortium and affiliate models When organizations lack the number of employees (typically fewer than 2000) to financially justify having their own EAP, a consortium model offers an alternative. An EAP consortium is a mutual agreement among organizations that collaborate to maximize resources as opposed to contracting individually. Affiliate models occur when a company has several offices and contracts services; the contractor may use affiliates and subcontractors. The affiliates, in this model, are those

EAP providers based on a fee-for-service or case-by-case basis. The goal with the affiliate model is to ensure that all employees are covered as deemed necessary.

Types of Interventions

EAPs provide a range of services from traditional alcohol and drug abuse treatment to holistic interventions geared toward stress management, other addictions (e.g., eating disorders, smoking cessation), work-life balance, and general well-being. These services can include assessment and referral models (one or two meetings), short-term intervention models (in which the number of meetings may be limited to 6–12 meetings per year), and long-term models (in which the number of meetings is not limited and depends on the needs of the client). Many of the services can be conducted in conjunction with other services to effectively address the employee's problems. [Table 1](#) provides examples of such interventions and services.

Challenges and Future Directions

The development, management, and delivery of employee assistance and counseling services continue to evolve and reflect the challenges of the contemporary workplace. Cultural and economic shifts, which influence the types and prevalence of employee problems, will affect the future configuration and operation of EAPs. Ultimately, these types of contemporary issues may affect worker productively and performance.

Employers are faced with new challenges related to the increased diversity in the workforce (e.g., gender, age, race, ethnicity, religion, sexual orientation,

disability). This diverse workforce has the potential to be more creative and productive than a homogeneous one, but employers have to overcome potential problems related to distrust and miscommunication that are often associated with diversity. EAPs can help by offering organizational diversity assessment and training and team dispute resolution.

The exponential growth in global work arrangements such as international mergers, subsidiaries, call centers, and subcontracting in the past few decades has introduced yet another set of challenges: how do families and communities cope with these new stressful conditions? How do they adjust to the pressures presented by the 24/7 economy? How do individuals cope with the blurring boundaries between work and private time? EAPs will be challenged with expanding their services to adjust to the demands of rapidly changing family and work structures.

Finally, the future of EAPs will also be affected by two conflicting trends in health and mental health care. One trend is motivated by the urgent need to contain the ever-rising health-care costs through contracting out services and using managed care systems that work diligently to contain costs by limiting types of services and supervising the service provision process. The other trend advocates a holistic health-care approach that focuses on treating the whole person by attending to the individual's mental, emotional, and physical well-being. The latter may require more in-house services and, in the short term, may be more costly, though in the long term its preventive aspects may contribute to cost containment. The resolution of these two trends may affect the scope and methods of service delivery that EAPs will provide in the future.

Table 1 EAP interventions and services

<i>Scope</i>	<i>Examples of EAP interventions and services</i>
Assessment	Diagnosis of presented problems and treatment plan
Informational	Referrals to appropriate services outside of the EAP
	Consultation and suggestions of solutions
Therapeutic	Counseling
	Therapy (short-term or long-term and family, couple, or individual)
	Clinical services
Preventive	Stress management
	Health and fitness programs
Educational	Training
	Personal development

The endocrine system is one of three control systems of the body, along with the nervous and immune/inflammatory systems. The classical definition of endocrinology was the discipline that dealt with hormones and the glands and target tissues involved in hormone secretion and action. Hormones were traditionally defined as chemical compounds synthesized and secreted by glands and transported by the bloodstream to their target organs. In this respect, a

hormone (from the Greek, meaning to excite) differs from a neurotransmitter, which is a chemical substance released from nerve terminals at synapses or neuromuscular junctions and which exerts its effects at postsynaptic or postjunctional receptors without entering the bloodstream. However, as illustrated extensively by the hypothalamic-pituitary-adrenal axis, some nerve cells also liberate their neurotransmitters into the bloodstream. Neurotransmitters released from nerve cells at neurohemal junctions are termed neurohormones (see **Neuroendocrine Systems**).

The endocrine system is under the control of the nervous system by way of hypothalamic control of the pituitary gland. In turn, hormones exert potent effects on brain differentiation and function. The immune and inflammatory system, too, is under endocrine as well as nervous control. In turn, leukocytes

and macrophages secrete factors termed cytokines (which include the interleukins, interferons, and tumor necrosis factor) that exert effects on the brain and the endocrine system.

The same chemical compound can have several different functions, serving as a neurotransmitter in the nervous system as well as a hormone through its transport by the circulation. It has long been accepted that the evolution of hormones is predominantly about their functions, which depend upon tissue-selective expression of hormone-specific receptors. Many hormones, neurohormones, and neurotransmitters exert local or paracrine functions – that is, they reach their target cells by regional diffusion to nearby cells. The recognition of the different mechanisms by which a molecule might act in the body (i.e., hormone, neurohormone, neurotransmitter, paracrine transmitter) and

the complex interaction between the three control systems mediated by chemical signaling have led to an explosion of knowledge in the past 100 years. This biomedical renaissance has been made even more exciting by the precision added through molecular genetic analysis of endocrine and other signaling mechanisms.

Diagnosis and Treatment of Endometriosis

Conclusion

Glossary

<i>Dyspareunia</i>	Pelvic pain during intercourse.
<i>Dysmenorrhea</i>	Excessive menstrual pain.
<i>Endometriosis</i>	An estrogen-dependent disease characterized by the presence of endometrial tissue in ectopic sites outside the uterus.
<i>Fibromyalgia</i>	Chronic widespread pain involving all four quadrants of the body and the presence of 11 of 18 tender points on examination.
<i>Interleukins (ILs)</i>	A class of peptides with immune actions. IL-15 and IL-18 activate macrophages

Natural killer (NK) cells

T helper (Th) cells

and are responsible for cell-mediated immunity and phagocyte-dependent protective responses. IL-4, IL-5, IL-6, IL-10, and IL-13 (together with granulocyte-macrophage colony stimulating factor), produced by T helper 2 cells, are responsible for antibody production, eosinophil activation, and inhibition of several macrophage functions.

Large granular lymphocytes with cytolytic and cytokine/chemokine production activities. NK cells are involved in the control of microbial infections and tumor development. The role of NK cells in autoimmunity or in inflammatory conditions is unclear.

CD4+ T lymphocytes that, by producing cytokines, play a key role in regulating immune response. Naïve Th cells can be differentiated into two specialized subsets: Th1 and Th2. Th1 cells produce cytokines, such as interferon (IFN)- γ , tumor necrosis factor (TNF)- α , and IL-1, IL-2, and IL-12. Th2 cells produce IL-4, IL-5, IL-6, IL-10, IL-13, and granulocyte-macrophage colony stimulating factor.

Endometriosis, the presence of a functional endometrium outside the uterine cavity, is a common chronic gynecological disorder occurring in 4–10% of women of reproductive age. Endometriosis is a recurrent

disease that may significantly impair the patient's quality of life. It is characterized by the presence of uterine endometrial tissue on the pelvic peritoneum, the ovaries, and the rectovaginal septum and more rarely in the pericardium, pleura, and even the brain. In the United States, endometriosis is the third most common gynecological disease that requires hospitalization and a leading cause of hysterectomy.

Although endometriosis was described over 300 years ago, its pathogenesis remains an enigma. At the time of clinical presentation, most women already have established disease and, therefore, it is very difficult to investigate the early developmental stages of the disorder. Ectopic endometrial tissue growth and inflammation are two pathophysiological features responsible for endometriosis-associated pelvic pain and infertility. Ectopic endometrial tissue responds to cyclic changes in gonadal hormones by proliferation and differentiation and by the local production of autocrine and paracrine factors. Therefore, endometriosis is an estrogen-dependent condition, with lesions undergoing regression during states of cessation of ovarian function, such as hypogonadal amenorrhea and menopause. Ectopic endometrium, however, appears to behave differently from its eutopic counterpart. Thus, endometriotic lesions are characterized by high local aromatization to estradiol biosynthesis and low estradiol inactivation compared with eutopic endometrium. Using laser-capture microdissection and a cDNA microarray with 9600 genes/expressed sequence tags (ESTs), a recent study showed that 904 genes/ESTs are differentially expressed in ectopic and eutopic endometrial tissue.

Pelvic endometriosis can be subdivided into three distinct entities: superficial peritoneal (and ovarian) endometriosis, cystic ovarian endometriosis, and deeply infiltrating endometriosis. Women with endometriosis and pelvic pain may also have chronic generalized pain and fatigue (i.e., fibromyalgia and/or chronic fatigue syndrome), as well as atopic and autoimmune disorders. It has been suggested that endometriosis may be associated with increased risk of ovarian cancer, non-Hodgkin lymphoma, and breast cancer. However, further epidemiological studies are necessary for the investigation of the possible association between endometriosis and cancer.

Etiology

The etiology of endometriosis is unclear; the most widely accepted hypothesis for its development is retrograde menstruation into the peritoneal cavity via the fallopian tubes and the subsequent attachment of endometrial cells to the peritoneal/ovarian surface. An alternative explanation is that the endometriosis

implants result from *in situ* metaplasia. Whichever mechanism is responsible, there are likely to be additional factors that determine whether a woman develops endometriosis. Indeed, susceptibility to endometriosis is thought to depend on the interaction of genetic, immunological, hormonal, and environmental factors. Therefore, it appears that endometriosis is a multifactorial genetic disorder, inherited as a complex genetic trait in which multiple genes conferring disease predisposition (including cancer-susceptibility genes and genes coding for cytochrome 450 enzymes, nuclear receptors, and immunological mediators) interact with one another and the environment to facilitate development of the disease.

Endometriosis and Pelvic Pain

Pelvic pain associated with endometriosis usually is cyclical; however, the pain may become continuous as the disease progresses. Indeed, it is common for any type of regional pain syndrome to eventually spread to become more systemic and involve the entire body (i.e., transform into fibromyalgia).

Little is known about the association between the endometriotic lesions and pain. Medical therapies aimed at the downregulation of ovarian function result in the elimination or reduction in size of endometriotic implants and the reduction of endometriosis-related pain in women. The surgical removal of the ectopic implants may alleviate pain symptoms in some women; however, the surgery may also fail to alleviate the pain.

It has been reported that pain is greater in women with deeply infiltrating endometriotic lesions in highly innervated areas than in women with more superficial lesions. Also, it has been suggested that the nerve fibers are closer to the endometriotic implants in women with pelvic pain than in women without pain, implicating the nervous system in endometriosis-related pain.

Endometriosis and Infertility

The mechanisms of endometriosis-associated infertility are not well understood. In advanced-stage endometriosis, pelvic adhesions distort normal pelvic anatomy and impair tubo-ovarian function. However, it seems that even mild disease may negatively affect oocyte quality and implantation. A meta-analysis of assisted reproduction studies showed that the pregnancy rate in women with endometriosis is approximately one-half that in women with tubal factor infertility. In women with endometriosis undergoing *in vitro* fertilization, the presence of auto-antibodies is associated with significantly lower pregnancy rates.

Endometriosis, Immune Function and Stress Response

There is increasing evidence that immunological factors play an important role in the pathogenesis of endometriosis. Women with endometriosis have an altered function of the peritoneal macrophages, natural killer cells, and lymphocytes, as well as changes in growth factors and inflammatory mediators in the peritoneal fluid.

Endometriosis is associated with the suppression of cell-mediated immunity and the stimulation of humoral immunity. Impaired natural killer cell activity resulting in the inadequate removal of refluxed menstrual debris may have a role in the development and maintenance of endometriotic implants. In endometriosis, macrophages are found in increased numbers in the peritoneal fluid, and although they would be expected to facilitate ectopic endometrial cell clearance, they appear in fact to support endometriotic lesions by producing growth factors and pro-inflammatory cytokines. These cytokines – interleukin (IL)-1, IL-8, tumor necrosis factor (TNF)- α , and interferon (INF)- γ – may in turn activate chemotactic factors, inducing infiltration of the peritoneum by T lymphocytes and macrophages. The immune mediators produced by these cells may promote the implantation and growth of ectopic endometrium by inducing its proliferation and angiogenesis. It is thus possible that in endometriosis a vicious circle is activated, with ectopic endometrial lesions causing inflammation and inflammatory mediators stimulating endometrial lesion growth.

Interestingly, decreased cellular immunity along with increased humoral immunity is also seen in patients with chronic fatigue syndrome and fibromyalgia, in people in other chronic stressful conditions, such as students taking examinations, prisoners from concentration camps, and spouses of Alzheimer's patients, and in animal studies of chronic stress (Table 1). Interestingly, a study of a symptomatic woman with endometriosis and her family, using

electroencephalography, digital skin temperature, electrodermal response, and electromyography, showed that endometriosis symptoms were associated with prolonged stress reactions. The study revealed that facts of family history and relationships for three generations set the stage for such stress reactions. The relation between endometriosis and stress is intriguing and has been poorly investigated. It is tempting to speculate that endometriosis may be associated with dysregulation of the stress system.

That endometriosis may have an autoimmune basis, associated with stress response dysregulation, is further supported by the finding that atopic diseases, such as allergies, asthma, and eczema are more frequent in women suffering from endometriosis. In addition, a higher incidence of autoimmune inflammatory disorders (rheumatoid arthritis, systemic lupus erythematosus, Sjögren's syndrome, multiple sclerosis, and autoimmune thyroid disease) is found in women with endometriosis. Of note, women with endometriosis are more likely to have allergies, asthma, and eczema if they also have fibromyalgia and/or chronic fatigue syndrome. In addition, family members of women with endometriosis have autoimmune inflammatory diseases, endocrine diseases, and chronic fatigue states, indicating that this spectrum of disorders may share a common genetic predisposition and underlying pathogenic mechanisms.

Peripheral Corticotropin Releasing Hormone and Endometriosis

In endometriosis, the implantation of ectopic endometrial tissue is associated with a local inflammatory reaction, including macrophage activation and the elevation of cytokines and growth factors. Corticotropin releasing hormone (CRH), the principal regulator of the hypothalamic-pituitary-adrenal axis, as well as its receptors, have been identified in various systems, such as the immune and female and male reproductive systems. Indeed, CRH-like immunoreactivity has been found in peripheral inflammatory sites and in a number of reproductive organs, including the ovaries and the endometrial glands. Therefore, immune and reproductive CRHs are forms of CRH found in peripheral tissues. Immune CRH plays a direct immunomodulatory role as an autocrine/paracrine mediator of inflammation. One of the early effects of immune CRH is the degranulation of mast cells and the release of histamine and several inflammatory cytokines. High numbers of activated mast cells are present in endometriosis sites, which are also strongly positive for CRH. Further studies are needed to clarify the possible role of peripheral CRH in the pathogenesis of endometriosis.

Table 1 Common immune changes in endometriosis, fibromyalgia, chronic fatigue syndrome, and other chronic stressful conditions^a

Diminished cellular immune responses	Decreased NK cell activity Decreased response to mitogenic activity Decreased Th1 activity
Increased humoral immune responses	Increased immunoglobulin production Increased Th2 activity

^aNK, natural killer; Th, T helper.

Diagnosis and Treatment of Endometriosis

The symptoms of endometriosis include dysmenorrhea, dyspareunia, pelvic pain, and infertility. Adhesions, which are often associated with endometriosis, can play a role in painful symptoms. On the other hand, endometriosis is detected in 2–50% of cases during laparoscopy in women with no symptoms.

The diagnosis of endometriosis is usually made by direct visualization of the pelvis during diagnostic laparoscopy because noninvasive diagnostic imaging techniques have a relatively low sensitivity. For this reason, the precise frequency of endometriosis in the general population is unknown, given that an unknown percentage of affected women are asymptomatic. The reported surgically diagnosed annual incidence is 1.3–1.6 per 1000 women ages 15–49.

The therapeutic strategy for endometriosis must be determined for each patient individually. The principal goal in treating endometriosis is the relief of symptoms, the amelioration of infertility, and the prevention or delay of disease progression. For women with pain, surgery usually provides temporary relief; symptoms recur in up to 75% of women within 2 years. Therefore, many women require repeated medical and surgical therapy to control the symptoms.

Pharmacological treatment options include non-steroidal anti-inflammatory agents and agents that suppress ovarian function and limit the growth and activity of endometriosis, such as gonadotropin-releasing (GnRH) analogs, androgenic/progestagen agents (danazol), combined oral contraceptives, and progestagens. However, currently available medical therapies are unsatisfactory, and they cannot be used for prolonged periods of time because of severe secondary side effects.

There is a need to develop new drugs to provide more efficient therapeutic alternatives that eliminate endometriotic lesions and prevent recurrences. Under investigation are new agents, such as aromatase inhibitors, selective estrogen receptor modulators, and progesterone receptor modulators.

The medical treatment for pain is not useful for infertility management. Infertility management includes controlled ovarian hyperstimulation and intra-uterine insemination or *in vitro* fertilization and embryo transfer.

Conclusion

Endometriosis is a common, estrogen-dependent, chronic gynecological disorder. It is characterized by the presence of uterine endometrial tissue outside

the uterine cavity. Endometriosis may present as superficial and/or deep pelvic peritoneal implants, adhesions, and ovarian cysts (endometriomas). The symptoms of endometriosis include pelvic pain and infertility. Affected women are at higher risk than the general population for developing fibromyalgia, chronic fatigue syndrome, autoimmune inflammatory diseases, and atopic diseases. The association between endometriosis and stress is an intriguing but poorly investigated issue. However, it is possible that endometriosis may be associated with the dysregulation of the stress system. Endometriosis requires multidisciplinary care and long-term follow-ups for the surveillance of associated disorders that may develop in susceptible women.

Enuresis

S K Anand and C D Berkowitz

Harbor-UCLA Medical Center, Torrance, CA, USA

© 2007 Elsevier Inc. All rights reserved.

This article is a revision of the previous edition article by S K Anand and C D Berkowitz, volume 2, pp 49–52, © 2000, Elsevier Inc.

during daytime while awake (10%), or both. The focus of this article is on nocturnal enuresis; diurnal enuresis is only minimally included. Although enuresis is a benign condition, many school-age children who experience bed wetting find it socially embarrassing and stressful. In some children, it may also lead to negative self-esteem.

Prevalence and Epidemiology

Etiology

Evaluation

Management

Prognosis

Glossary

Enuresis

Involuntary passage of urine in bed or clothes in children whose age and development would suggest achievement of bladder control.

Enuresis refers to involuntary passage of urine in bed or clothes in children whose age and development would suggest achievement of bladder control. It may be nocturnal, only during sleep (80%), diurnal,

Prevalence and Epidemiology

At age 6 years, 10–15% children wet the bed at least once monthly, with some wetting nightly. Beyond 6 years there is a spontaneous resolution rate of approximately 15% per year. In adolescents older than 15 years and in adults, the prevalence of enuresis is reported to be between 1 and 2%. The disorder is more common in boys than girls. Enuresis is prevalent in all areas of the world with similar frequency. The disorder is termed primary enuresis in 80% of enuretic children if they have never achieved sustained dryness, and secondary enuresis in the remainder when wetting recurs after 6 months of dryness. There is a strong genetic predisposition for enuresis. The probability of enuresis is nearly 75% if both parents are enuretic, and 45% if one parent is affected. The concordance for identical twins is 68% and for fraternal

twins, 36%. Enuresis is more common in children with low IQ scores, attention deficit disorder, fecal incontinence, low socioeconomic status, large family size, or single-parent families, and in institutionalized children.

Etiology

The etiology of nocturnal enuresis is unknown except for the genetic predisposition described previously. Most children with primary enuresis are biologically and psychologically normal except that during sleep they are unable to recognize the sensation of a full bladder and fail to awaken to urinate in the toilet. Several factors have been reported to contribute to enuresis; these include delayed maturation of physiological control, urodynamic changes, sleep disturbance, alterations in nocturnal vasopressin secretion, psychological factors, and organic medical or urological disorders.

Delayed Maturation

Until the age of 5 years, variability or delay in maturation of urinary control is often considered the basis of enuresis. Many experts believe that beyond age 5 years, however, this is an unsatisfactory explanation, especially if a child can achieve daytime control. Nevertheless, others believe that a disorder that affects 10–15% of otherwise normal children and that has no known long-term medical consequences except social embarrassment must be considered in the realm of variability or delay in micturition maturation.

Urodynamic Changes

In the majority of enuretic children, the actual bladder capacity is normal; however, the functional bladder capacity (volume at which bladder empties itself during the night) is reduced in some. Many children with diurnal enuresis have unstable bladder (due to involuntary bladder contractions), but bladder instability is not an important factor in nocturnal enuresis.

Sleep Disturbance

The fact that enuresis occurs during sleep suggests that a disturbance in normal sleep may cause enuresis. Also, parents of enuretic children often report that the child sleeps too deeply and is difficult to awaken during the night. Some studies have reported that enuretic children have had impaired arousal to loud sounds during sleep. However, objective findings in most studies demonstrate normal sleep pattern and do not document that either the children sleep too deeply or are more difficult to awaken.

Nocturnal Vasopressin Deficiency/Polyuria

Normal children have an increase in vasopressin (AVP) secretion during the night, which results in decreased urine volume. In some children with enuresis, AVP secretion during the night does not increase, thus leading to larger volume of urine and enuresis. Desmopressin (DDAVP) may be especially useful in treating such children.

Psychological Factors

During acute stressful states such as the loss of a parent or addition of a sibling, transient recurrence of enuresis is often observed. The vast majority of children with nocturnal enuresis, however, as stated earlier, are psychologically normal. The occasional emotional problems noted in such children are generally due to the consequences of enuresis (e.g., social embarrassment or punitive measures to control enuresis) rather than the cause of enuresis. Once enuresis is cured, these emotional problems and the child's self-esteem generally improve and do not deteriorate or result in substitute symptoms as might be expected if enuresis were the primary symptom of an emotional disorder.

Organic Medical or Urological Disorders

Organic medical or urological disorders are the cause of enuresis in less than 5% of affected children and include urinary tract infection, diabetes mellitus, diabetes insipidus, sickle cell anemia, cystic kidney disease, and other urological disorders. Even enuretic patients with these disorders eventually gain nocturnal bladder control by adolescence.

Miscellaneous Causes

Enuresis in children and adults may accompany obstructive sleep apnea; resolution usually follows relief of the obstruction. Caffeine intake is sometimes associated with enuresis in adults and should be reduced or stopped before initiating other treatments.

Evaluation

A thorough history should be obtained, especially for genetic predisposition and medical or urological disorders (including dysfunctional voiding) that may result in enuresis. History should be sought for previous efforts to stop enuresis and reasons for consultation at this point in time (e.g., ruling out serious medical problems, child would not sleep overnight at a friend's house). Finally, the motivation of the child and family to implement various measures to stop enuresis should be assessed.

A complete physical examination should be performed, including growth parameters and blood pressure. Abdomen should be examined for organomegaly, bladder distention, and fecal impaction. Genitalia should be examined for any genitourinary abnormalities such as labial adhesion. Rectal examination may be needed to evaluate rectal tone. The lower back should be examined for dimples, sinuses, a tuft of hair, or any spinal abnormalities. If necessary, the child's neurodevelopment should be assessed.

Urinalysis of a freshly voided, first morning specimen is the only laboratory test usually necessary; the specimen should be assessed for specific gravity, protein, blood, and abnormal cellular elements. Blood tests (e.g., for renal function, electrolytes) are usually unnecessary. Similarly most children do not require any radiological studies. In children with diurnal enuresis, ultrasound of the kidneys and bladder as well as cystometry may be sometimes indicated. Children with urinary tract infection as well as other neurological or medical disorders may require special studies.

Management

Treatment begins with the reassurance and education that enuresis is not a serious renal or urological problem, that it is not the child's fault or due to laziness, and that eventually, even untreated, the disorder will resolve in the vast majority of patients. The rationale for treatment is that cure of enuresis is often accompanied by improvement in child's self-esteem. The two main methods of management are based on behavior modification (i.e., conditioning therapy) or drug treatment, and these modalities may be used in conjunction with each other. Encouraging the child to take responsibility for solving the problem is essential for success. This implies the need for motivation on the part of the child to learn to get out of bed and go to the toilet in the middle of the night, as well as a commitment to help with laundry and changing sheets. A reward system, like using a star chart, may be useful but must be used in addition to other interventions. Fluid restriction alone is ineffective; nevertheless, limiting fluid intake for 2 h before bedtime, urinating before going to bed, and improving access to a toilet are sensible, useful measures. Although various management plans discussed previously and in further detail in the following sections have been shown to be effective in a reproducible fashion, evaluation of various measures as a recommendation for any individual child has been difficult because there is a spontaneous cure rate of 15% every year. In addition, in many children, there

is cessation of enuresis after the first physician visit and reassurance.

Behavior Modification, i.e., Conditioning Therapy

The principle behind behavior therapy is that the child must get up during the night and use the toilet, before or as soon as urination starts. For behavior therapy to succeed, the child and parents must be motivated to implement the techniques discussed here; otherwise, the therapy is doomed to failure.

Self-awakening or parent-awakening program The technique of self-awakening consists of rehearsing a sequence of steps: (1) the child is asleep and it is the middle of night; (2) the child perceives that the bladder is full and that he or she needs to go to bathroom; (3) the child goes to the bathroom; (4) the child sits on the toilet and urinates; (5) the child goes back to bed and falls asleep. The steps can be rehearsed by getting in the bed sometime before regular sleep hours or even during the day. The parent-awakening program is indicated if self-awakening does not succeed; this technique still requires the child's participation. The parent's role is in awakening the child at a set hour. The child still must complete steps 2 to 5. This technique is most useful in the adolescent and older elementary school children.

Enuresis alarms Enuresis alarms are used as an adjunct to self-awakening. They are triggered by wetness, when only a few drops of urine have been voided. The child must inhibit further urination, get up, and complete steps 3 to 5 described in the preceding section. With practice, bladder distention does not lead to an immediate urge to urinate. This gives the child time to complete the steps. Newer versions of alarms that are transistorized and/or vibrate instead of giving a sound signal are available at relatively modest prices.

Conditioning therapy including self-awakening and alarm systems has the highest likelihood of long-term success in treating enuresis, with rates reported to be as high as 50–80%. Acupuncture, hypnosis, and psychotherapy have been reported to be of benefit, but there are no good trials demonstrating their effectiveness.

Drug Therapy

Pharmacological therapy for nocturnal enuresis includes tricyclic antidepressants (TCA) and DDAVP. Anticholinergics such as oxybutynin are more effective for diurnal enuresis than for nocturnal enuresis. Drug therapy is generally safe and well tolerated, but

like all medications has potential side effects and complications.

TCA Imipramine has been the principal TCA used for enuresis, but other TCAs are also effective. The mechanism of action is unknown. The starting dose of imipramine is 25 mg (which may be increased to a maximum of 50 mg for 8- to 12-year-olds and 75 mg for >12 years old) 1 h before bed time. A trial period of 2 to 4 weeks is adequate to assess effectiveness. The initial success rate is about 40–60% with a relapse rate of 50–70% upon discontinuation.

DDAVP DDAVP, a synthetic vasopressin analog (1-(3-mercaptopropionic acid)-8-D-arginine vasopressin monoacetate (salt) trihydrate), works by reducing the amount of urinary output during the night. The overall effectiveness is about 25–33% (range of 12–86%) for children becoming totally dry for 14 or more consecutive nights. DDAVP more often reduces urine volume and the number of wet nights per week, but does not make children totally dry. Most children (up to 90%) relapse after discontinuation of DDAVP. It may be administered intranasally or as a tablet; both appear equally effective.

Prognosis

The prognosis for children with enuresis is generally good. Reassurance to the family that enuresis is not due to a serious renal, medical, or emotional problem and that it has a spontaneous cure rate of 15% per year is very helpful. Medical management improves symptoms in more than 70% of children.

Historical Background

The Impact of Environmental Factors on Stressors

Differential Exposure and Vulnerability to Environmental Stressors

Glossary

Differential exposure hypothesis

The contention that specific statuses or roles are associated with greater or lesser levels of stressors that arise out of the conditions of life and which, in turn, affect levels of psychological distress.

<i>Differential vulnerability hypothesis</i>	Argument that elevated levels of distress among individuals in disadvantaged statuses reflect their greater responsiveness to stressors; that is, in two social groups exposed to the same levels of stressors, distress will be higher among those people in the disadvantaged statuses.
<i>Environmental factors</i>	Social or economic circumstances that affect exposure to stressors.
<i>Social causation</i>	A model that suggests that people in socially disadvantaged statuses will be exposed to more stressors that, in turn, result in more distress or disorder.
<i>Social selection</i>	A model that suggests that people with high levels of stress in their lives are more likely to experience mental health problems and consequently are more likely to occupy disadvantaged statuses.
<i>Stress process paradigm</i>	A model that describes how stressors manifest themselves in distress or disorder. It postulates the existence of three factors that either mediate or moderate the effects of stressors on distress or disorder: psychosocial resources, coping resources and strategies, and social supports. The model also specifies how environmental factors influence all other variables in the paradigm.

Historical Background

There is a vast body of research literature on the impact of social and economic factors on physical and mental health problems. In general, these studies have demonstrated that individuals' social locations in society, in terms of their social statuses and social roles, have important implications for both the kinds and levels of stressors to which they are exposed. Indeed, one of the most important contributions of the sociology of mental health has been to demonstrate conclusively that stressors are not experienced randomly by individuals but, rather, that there is a social distribution of stressors. This perspective has emerged out of a number of theoretical and empirical developments.

Much of the work on the social distribution of stressors has its intellectual origins in the work of Bruce and Barbara Dohrenwend in the 1970s. They observed that exposure to stressful life events was correlated positively with symptoms of mental illness. They argued that the higher rates of psychological impairment found among members of socially disadvantaged groups might be explained by their greater exposure to life events. The underlying assumption of this explanatory model was that social causation processes were operating: differences in social statuses

and social roles produce variations in the experience of life events that result in different rates of mental health problems among these social groups.

For the next decade, social scientists exhaustively studied the relationships among environmental factors, stressful life events, and psychological distress and disorder. At least three major themes emerged from this work. First, a conceptual paradigm emerged for examining the interplay among environmental factors, stressors, mediators, and mental health outcomes. Second, it became clear that stressful life events constituted only one kind of stressor and that research needed to identify and study other types. Third, there was general agreement with the notion that the distribution of stressors is socially patterned.

The Stress Process

Several researchers working independently in the 1980s developed conceptual models that enable us to better understand how socially induced stressors manifest themselves in psychological distress, symptoms of psychiatric disorder, or in other dysfunctions or health problem. All of these models focus on the association between stressful life events and their distressful manifestations (psychological distress, psychiatric disorder, etc.). These models also postulate the existence of three important factors that either mediate or moderate the effects of stressors on distress or disorder. These include psychosocial resources, coping resources and strategies, and social supports. In recent years, this model has been elaborated by specifying the kinds of environmental factors – primarily social and economic variables associated with social statuses and roles – that influence all other variables in the paradigm. This paradigm has provided social scientists and epidemiologists with a conceptual framework for studying the effects of environmental factors on stressors as well as on all other components of the model.

The Stress Universe

Throughout the 1970s and early 1980s, most of the research on environmental sources of stressors focused on life-change events. The most widely used measures of life stress were events checklists that usually contained from 30 to 100 events that represented potential changes in people's lives. These included events such as the death of a loved one, marital separation or divorce, job loss, and geographical moves. Over time, however, two developments substantially altered the study of environmental stressors. First, it became clear to researchers who were studying the stress process that the association between eventful stressors and distress was modest at best. For many

researchers, this suggested that stressors were not being measured comprehensively. Accordingly, they expanded life events inventories to include events that were not life changes, but which included other difficulties such as family conflicts, work conflicts, and financial difficulties. In part, the inclusion of these events reflected the realization among many researchers that stress often arises in the context of individuals' work and family roles. Second, investigations of intra-event variability in stressful life events revealed that life events inventories included ongoing or chronic stressors (such as family conflict, marital difficulties, and financial problems) as well as eventful stressors.

These considerations led researchers to develop more extensive strategies to measure a broader array of life stressors than had previously been the case. Perhaps the most comprehensive consideration of the many dimensions of life stress was presented by Wheaton. He distinguished among various concepts of stressors, including chronic stress, daily hassles, macro events, and traumatic events. In doing so, he presented a scheme for arraying these different stressors on a continuum ranging from sudden traumatic experiences and life change events at the discrete end to chronic stressors that are more continuous in nature. Wheaton demonstrated two important properties of these various dimensions of the stress universe: (1) they are relatively independent of one another and therefore are unlikely to be empirically confounded with one another and (2) they each have significant independent effects on various measures of physical and mental health outcomes. These findings suggest that any comprehensive attempt to estimate the impact of life stressors on health outcomes requires that we measure an array of stressors that includes both discrete life experiences and more chronic or ongoing stressors.

The Social Distribution of Stressors

Early research by Bruce and Barbara Dohrenwend and by George Brown and his colleagues on life events clearly established that socially induced stressors exerted important influences on various measures of mental health outcomes. What seemed particularly interesting was that the socially disadvantaged groups with the highest levels of distress and disorder also appeared to be exposed to the most stressful life events. This led to the hypothesis that social differences in distress and disorder might be accounted for by variations in either exposure or vulnerability to social stressors.

Subsequently, in a seminal article on the sociological study of stress, Pearlin argued for the need to systematically investigate the ways in which social

structure affects individuals' exposure to stressors. Essentially, Pearlin asserted that the roles and statuses that people occupy in their everyday lives have important consequences for the kinds of stressors to which they are exposed and the frequency with which this occurs. In short, he argued that accounting for the impact of environmental factors is crucial for understanding the ways in which individuals experience social stressors.

This point has been made even more salient by Turner, Wheaton, and Lloyd in their paper on the epidemiology of social stress. Their findings from a large community study reveal that younger people are more exposed to a variety of stressors than are older respondents. They also find this pattern among women compared to men, unmarried people compared to married people, and individuals in lower socioeconomic status (SES) positions compared to those in higher SES positions. In their view, this clearly indicates that stressors are not experienced randomly in the population. Quite the contrary, they asserted that their results reveal that there is a social distribution of stressors that is characterized by greater exposure among members of disadvantaged social groups.

The Impact of Environmental Factors on Stressors

In thinking about the social distribution of stressors, social scientists have focused primarily on three major environmental determinants: social statuses, social roles, and the ambient environment. Most formulations of the stress process model take the view that individuals' locations in the structure of society place them at greater or lesser risk of encountering stressors. These locations are defined by the various statuses that individuals hold and by the various social roles they occupy. In addition, there are more ambient characteristics of the social environment that are not specific to statuses or roles but that may generate stressful experiences for individuals.

Social Statuses

In the literature, individuals' positions in the structure of society are often defined by six major status characteristics: age, gender, marital status, race/ethnicity, employment status, and SES. Each of these environmental factors is associated with differential exposure to stressful experiences.

Age There appears to be substantial agreement among researchers that exposure to stressful experiences declines with age. Whether the stressors in ques-

tion are life events or chronic role strains, younger people report significantly more stress than do the elderly. Moreover, economic hardship tends to decline with age as does marital conflict in marriages that stay intact. Despite these findings, it is not yet clear whether the impact of age on exposure to stressors is a function of maturation processes, birth cohort or generational effects, or life-cycle processes.

Gender Studies of gender differences in exposure to stressors have generated inconsistent findings. Some research concludes that women experience more stressful life events than men, whereas other research finds no differences. Turner and Avison conducted one of the more comprehensive studies of gender exposure to various dimensions of stress. Women report more stressful life events than men, but they experience fewer lifetime traumatic events and less discrimination stress. Women and men do not differ in their exposure to chronic stressors. When these various dimensions of stress were considered cumulatively, they found that men experience greater exposure compared to women but that this difference is relatively small. Turner and Avison concluded that these small gender variations in exposure to stressors are unlikely to account for gender differences in psychological distress.

Although other researchers reported that women are more exposed than men to chronic strains due to financial hardship, workplace difficulties, and role overload associated with parenting and work, these differences are difficult to separate from the gendered roles that women and men play in the workplace and in the household division of labor. Indeed, one of the lessons of stress research in the sociology of mental health is that gender conditions the effects of a variety of roles and statuses on the exposure to stress.

Marital status One of the more robust findings in the study of social stress is the observation that married individuals experience considerably fewer stressors than either never married or formerly married individuals. This pattern can be observed for chronic strains as well as for stressful life events. Unlike age and gender, however, the causal direction of the relationship between marital status and stressful experience is open to competing interpretations. A social selection interpretation suggests that people with high levels of stress in their lives are less likely to marry or, if they do so, they are more likely to separate and divorce. A social causation interpretation suggests that people who have never married and those who have separated or divorced are more likely to experience an array of life events and chronic strains than are the married.

Some longitudinal research indicates that divorce leads to elevated levels of depression and that this change is accounted for by a decline in living standard, economic difficulties, and a reduction in social support. Even if the end of a marriage provides some escape from a stressful situation, divorce is accompanied by life stress that has depressive consequences. Other studies also report significant increases in psychological distress among the marital-ly disrupted over and above their predivorce levels, but find virtually no evidence that changes in financial stressors, changes in role demands, or changes in geographic location mediate the relationship between marital disruption and distress. These are reflective of longitudinal studies on marital disruption and remarriage insofar as they generate few consistent findings other than the observations that marital disruption is associated with elevated psychological distress and that remarriage results in only a partial reduction in this elevation.

Race and ethnicity Studies of racial and ethnic variations exposure to stressors are relatively recent in the literature. There is general agreement that experiences of discrimination constitute an important set of stressors for African Americans, Hispanic Americans, and American Indians. In addition, stressors arising out of the social disadvantages of these groups have also been observed. Among Asian Americans, the experience of discrimination and the stress of migration have been noted as important threats to their mental health.

Turner and Avison systematically examined differences between African Americans and Whites in the United States in exposure to stressors. Across five different dimensions (recent life events, chronic stressors, total lifetime major events, lifetime major discrimination, and daily discrimination), African Americans experience significantly more stress than do Whites. Indeed, the cumulative difference between African Americans and Whites in exposure to stress is more than 0.5 standard deviation.

It is interesting to note, however, that these elevated levels of stressors among racial and ethnic minority members do not necessarily translate into higher rates of distress or disorder for all groups. In their review of this issue, Williams and Harris-Reid concluded that African Americans have lower prevalence rates of psychiatric disorders than do Whites. The data are inconsistent when comparing Whites with Hispanic Americans or Asian Americans. What little data exist about the epidemiology of mental health among American Indians suggests that their rates of disorder, especially depression and alcohol abuse, are elevated.

It is difficult to interpret the meaning of these findings. Lower rates of disorder in the face of elevated levels of distress suggests that some racial and ethnic group may be less vulnerable than others to these stressors or that countervailing effects of psychosocial resources may reduce the impact of stressors on their mental health. Turner and Avison suggested that African Americans may exhibit a response tendency in which they underreport infrequent or mild experiences of distress, thus leading to an underestimation of their levels of distress. They demonstrate that once this tendency is taken into account, there is clear evidence that African Americans' elevated exposure to stress manifests itself in significantly higher distress.

Employment status Research leaves little doubt that the unemployed experience more negative mental health outcomes than do the employed. The evidence of this correlation is most clear for outcomes such as symptoms of depression and anxiety and measures of psychological distress. Longitudinal studies support the conclusion that job loss results in higher levels of mental health symptoms.

Studies of the factors that intervene between individuals' job losses and their health problems have identified at least two major sources of environmental stressors that mediate this relationship. Some researchers have shown that job loss and unemployment create financial strains that lead to mental health problems. Others have examined the mediating role of marital and family conflict. These studies report that unemployment leads to increasing conflicts between the unemployed worker and other family members. Some researchers have suggested that the elevated levels of distress observed among women whose husbands are experiencing job-related stress may be consistent with the costs of caring hypothesis described earlier.

Socioeconomic status Although there is general agreement that SES and mental illness are inversely correlated and that exposure to stressors are a major determinant of mental health problems, there has been surprisingly little consensus among researchers about the SES-stress relationship. Whether SES is measured by some combination of education and income or by occupational prestige among those with jobs, contradictory results emerge. These inconsistent findings have led some researchers to argue that it is not stress exposure that produces higher rates of mental illness among individuals with lower SES. Rather, they suggest that the impact of stressors on mental illness is more substantial among low-SES than high-SES individuals. In other words, they argue that lower-class individuals are differentially vulnerable to stressors. It seems clear that this debate with

respect to the influence of SES has not been resolved. Nevertheless, more recent studies suggest that when stressors are comprehensively measured, there is a significant social-class gradient in exposure to stress.

Some of the most compelling evidence of the effects of economic hardship on marital relationships has been presented in studies of families during the Great Depression of the 1930s. This work clearly indicates that economic difficulties increase marital tensions in most families and especially in those that were most vulnerable prior to the economic hardship. Similar findings have been reported in studies of families whose lives were affected by the farm crises of the 1980s.

Social Roles

A central focus of much research on the stress process has been on the ways in which the social roles that individuals occupy expose them to stressors. Pearlin described these role strains in rich detail. For Pearlin, several types of stress may arise from role occupancy: excessive demands of certain roles, inequities in rewards, the failure of reciprocity in roles, role conflict, role captivity, and role restructuring. These various types of stress are important sources of stress that may manifest themselves in symptoms of distress or disorder. These kinds of environmental stressors have been studied most intensively in investigations of family roles and work roles.

Family roles Recent research on the family and mental health has focused on family structure in terms of the intersection of marital status and parenthood. In this context, there has been intense interest in the impact of single parenthood on symptoms of distress. Results consistently show higher levels of distress among single mothers than among married mothers. These studies of single parenthood clearly reveal that family structure and the roles embedded in that structure are important determinants of women's mental health.

Research indicates that separation and divorce trigger chronic stressors such as income reduction and housing relocation. In addition, the divorced experienced more life events than the married, particularly negative events involving loss. When children are involved, there may be additional strains associated with separation or divorce. The custodial parent, usually the mother, assumes many household, financial, and emotional responsibilities previously shared by two parents.

The work role In addition to examining how differences in employment or work status influence exposure to stressors and subsequent mental health

outcomes, social scientists have become aware of the importance of understanding how experiences in the work role are related to stress and health. Despite the observation that being employed generally has positive psychosocial consequences for individuals, not all employment circumstances are the same. Indeed, there are important variations in the stressors associated with any particular work situation. Work exposes individuals to various kinds of stressful experiences and provides different kinds of rewards for different people – financial rewards, self-esteem, a sense of control over one's life, and so on. It seems, then, that the net effect of paid employment for any individual will depend on the balance of these costs and benefits.

A number of recent contributions to the study of work and mental health have provided some useful models for this kind of research. In her comprehensive review of the literature on the interplay between work and family, Menaghan demonstrated clearly that work-related stressors are significantly associated with the mental health of family members. Other researchers have convincingly documented how role overload and the sense of personal power have important implications for the effects of women's employment on their mental health. Some investigations have shown how job characteristics such as full-time versus part-time work and substantive complexity have significant effects on mental health.

The intersection of work and family roles Research on work and family stress among women suggests a number of ways in which work and family roles interact in their effects on psychological distress and depression. These studies highlight the importance of considering both family stressors to which women are exposed and work-related stress.

Relatively few studies have examined how single parenthood and paid employment interact in their impact on mental health problems. The studies that have investigated this issue conclude that differences between single-parent families and two-parent families in role obligations and opportunities may have significant effects on the balance between work and family responsibilities. For married mothers, paid employment may be more easily integrated into daily family life. The presence of a spouse provides the opportunity to share some of the child-care responsibilities. Alternatively, dual-income families have more funds for outside child care or paid assistance in the home.

Employment for single-parent mothers may represent more of a pressing responsibility than an opportunity for achievement and development. Most single-parent families live in poverty or near poverty.

In such circumstances, although paid employment may alleviate some of the most pressing financial strains, other strains persist. Moreover, when single mothers obtain employment, it is common for them to also bear the continued sole responsibility for the care and nurturance of their children. Such dual demands may generate a cost to employment – role overload.

Under these circumstances, it seems probable that fewer psychosocial rewards associated with employment (greater self-esteem, self-efficacy, or social support) will accrue to single mothers. This is all the more likely to be the case because single parents may be constrained to select jobs that are not their first choice but that, instead, are near their homes or have hours of work that fit with their children's schedules or with the availability of child care.

Ambient Strains

Not all stressors are associated with statuses and roles. Ambient strains that are not attributable to a specific role but, rather, are diffuse in nature and have a variety of sources. These include experiences such as living through an economic recession, living in unsafe housing, or living in a dangerous neighborhood. Some studies have demonstrated that ambient strains associated with the neighborhoods in which adolescents live magnify the impact of other stressors on their mental health. Other studies make the same point with respect to the ambient effect of economic environments.

Differential Exposure and Vulnerability to Environmental Stressors

An important issue has been to test the relative importance of differential exposure and differential vulnerability to stressors as explanations of the differences in psychological distress by social status or social role. The differential exposure hypothesis contends that specific statuses or roles are associated with greater or lesser levels of stressors that arise out of the conditions of life and which, in turn, affect levels of psychological distress. For example, applying this argument to marital status, the hypothesis is that the transition from marriage to separation or divorce brings with it significant increases in exposure to financial strains, role overload, and other types of stressors. This increase in the burden of stress experienced by the separated or divorced people translates into elevated levels of mental health problems. Conversely, individuals who remain married experience far fewer stressful circumstances and, accordingly, have lower levels of psychological distress.

The competing explanation, the differential vulnerability hypothesis, argues that elevated levels of distress among individuals in certain statuses reflect their greater responsiveness to stressors. Such increased responsiveness or vulnerability to stressors has been attributed to a number of different sources. These include dimensions of personal and social competence, such as self-efficacy, that contribute to individuals' greater or lesser resilience in the face of stress and access to coping resources that moderate stressful experiences. The most recent work on this debate has been conducted by Turner, Wheaton, and Lloyd. Their investigation of age, gender, marital status, and SES reveals little evidence that any of the differences associated with these social statuses in distress or disorder can be attributed to differential vulnerability. Instead, they found that observed variations in mental health outcomes are due largely to different levels of exposure to stressors. They and others argue that the use of a more comprehensive measure of stressors that includes life events and chronic strains is likely to better estimate actual exposure and to avoid the error of attributing unmeasured differential exposure to differential vulnerability.

Theories of Effects of Stressors on Performance
Patterns of Stressor Impairment
Compensatory Control under Stress
Latent Degradation under Stress

Glossary

<i>Compensatory control</i>	A general adaptive response to stress serving to protect high-priority goals from disruption.
<i>Costs</i>	Effort or other resources used to achieve task goals.
<i>Environmental stressors</i>	Identifiable external conditions that pose a threat to the performance of subjective state, such as noise, heat, and time pressure.
<i>Human performance</i>	The effectiveness of behavior in relation to specific task demands and goals, assumed to reflect the operation of underlying mental processes.
<i>Latent degradation</i>	The effects of performance impairment not necessarily manifested in disruption of primary task activities.
<i>Short-term memory (STM)</i>	General label used to describe memory for very recent events, referring to the storage of information over brief periods (typically 10–20 s).
<i>Working memory (WM)</i>	Cognitive system acting as a “mental workspace” for manipulating information necessary for carrying out current processing and problem solving tasks, comprising both storage and attention/control components.

Human performance refers to the effectiveness of task activity in relation to goals. This assumes a focus on the primary mental processes that underlie controlled human action, particularly in tasks requiring the use of memory, attention, decision making, and perceptual-motor skills. A concern with the effects of stress on human performance has a long history in psychology, driven by both practical and theoretical issues. It has been known since the 1970s that the nature of the task is a strong determinant of how performance will be affected; it has also recently become clear that there is a general problem that affects the performance of all tasks. The key to understanding this appears to be to consider the goals that underlie behavior. It is not surprising that goals change under extreme stress away from the current task and toward a concern with bodily states or emergency reactions. In more everyday contexts, this implies a need to examine the strategies used to manage goal-relevant information and the factors that determine changes in goals. This has not always been done in research in this area. In what follows, I discuss the theoretical background to research on stress and performance, review the evidence for different patterns of disruption across various task and performance criteria, and show how an adaptive regulatory perspective enhances our understanding of the nature of the problem.

Theories of Effects of Stressors on Performance

Stressors have traditionally been considered as having one of two kinds of effect on performance: distraction or arousal. Early research on the effects of what we now consider stressors (e.g., loud noises) assumed a broadly distraction kind of theory. In general, apart from transient effects, such experiments were spectacularly unsuccessful in demonstrating any effects on complex performance – including tests of intelligence, memory, and skill. Not until the mid-1950s, with the application of information processing concepts to psychology, did theory have much of a part to play in this kind of research. More recent treatments (triggered by the seminal work of Donald Broadbent and his colleagues) has recognized that the effects of stressors may be masked, or compensated for, by the built-in redundancy and strategy options available to the cognitive system. Broadbent argued that it should be possible to demonstrate the effects of stressors by designing tasks that effectively stretched this regulatory process, for example, by presenting information rapidly and without breaks or by making critical events rare and unpredictable in time and place (e.g., serial reaction and vigilance tasks).

In the distraction theory, environmental events were thought to compete for attention through either their strong stimulus qualities (noise or heat) or their impact on bodily states (causing anxiety and other emotional reactions). In its modern form, the distraction view was developed most fully in Broadbent's influential filter theory. For example, noise was thought to impair task-relevant operations by capturing selective attention. This involuntary attention to the noise source interrupted the effective intake of relevant task information and gave rise to processing errors. The distraction theory is best supported by studies of intermittent noise, which impairs performance in the few seconds following each burst. In general, however, the distraction view has been thought to offer a less convincing explanation of the effects of both continuous noise and of other stressors, such as sleep deprivation, not so readily identified with external events.

As an alternative to distraction theory, the arousal theory of stress and performance was developed in the 1960s following the generally accepted view of the day that arousal was a unitary, nonspecific brain process. The application of arousal theory to stress effects was based mainly on the systematic studies of combined effects of stressors carried out in Cambridge, UK. This made extensive use of the five-choice serial reaction task, in which subjects were required to respond to a continuous stream of lights coming on by tapping one of the five metal plates

corresponding to the lights. This task showed impairment under noise and sleep deprivation and improvement when subjects were given incentives to do well. However, performance under noise improved somewhat when subjects were also sleep deprived, whereas incentives made their effects worse. These interactions between stressors were regarded as supporting the arousal theory of stressors because they appeared to show that impairment could be caused by both understimulation (sleep deprivation) and overstimulation (noise). However, the assumptions concerning the nature of arousal could not be convincingly demonstrated independently of the task itself. For example, there is no direct evidence that noise is arousing in a physiological sense, except in terms of the transient startle pattern at the onset. Increased arousal under noise is typically found only when people are carrying out cognitive tasks, and then only when they are concerned to prevent performance decrements occurring. In addition, it is clear from developments in physiological theory that arousal is more complex than previously assumed – more specific and linked to task processes. In sum, it has proved to be inadequate as a general theory of effects of stress.

Patterns of Stressor Impairment

The central approach to the understanding of stress effects presented in this article focuses on the problem of managing the general threat to task goals through adaptive changes in behavior. However, as I mentioned earlier, different stressors also appear to pose specific threats for tasks, depending on their information processing requirements. An analysis of stress effects on performance carried out in the 1980s found specific patterns of decrement across different indicators of performance and strategy. Some stressors were more likely to impair performance on one kind of task and others on a different kind. For example, loud noise typically impairs performance on tasks that require accuracy, short-term memory (STM), or problem solving. Sleep deprivation causes impairment on tasks that require accuracy, speed, and a high level of selective attention, as well as having more general effects on memory. Both noise and sleep deprivation have effects that are more pronounced under fatigue conditions (when tasks involve long periods of work without breaks). Working in hot conditions has widespread effects on most aspects of performance, especially tasks involving more complex decision making. The effects are related to the exposure time and effective temperature, but, unlike noise, do not appear to increase with time at work.

The set of indicators used in this analysis included general alertness, selectivity of attention, speed versus

accuracy, and STM. With changes in cognitive theory over the intervening period and the experience of the effects in real work tasks, some changes to this list are needed. General alertness no longer appears to have strong diagnostic value because it is likely to be involved in all active regulatory behavior. The mechanisms underlying STM have undergone considerable evolution with the development of working memory (WM) theory by Baddeley and colleagues. In addition, there is a need for a new analysis, which takes into account differential effects of regulatory activity. However, even with these caveats, changes in these performance indicators may be seen as a profile of the sorts of information-processing problems that different stress conditions may give rise to. The most general pattern of decrement is associated with environmental factors, such as noise, danger, or social evaluation, that give rise to subjective states of threat or anxiety. This may be regarded as the modal stress pattern involving a subjective state of high activation, high selectivity of attention, a preference for speed over accuracy, and reduced WM function. Decrements are more common on tasks of long duration, especially where the continued use of WM is central to maintaining the flow of the work. Selective attention is normally very effective, unless response is required to a number of different events or subtasks, in which case only the most important may be maintained. A familiar effect of such stressors is narrowed attention, in which the high-priority features of tasks are maintained and secondary aspects are neglected. Such an effect has been observed for a wide range of stress states, including noise, high workload, threat of shock, danger, and most forms of induced anxiety. Other stressors are associated with different kinds of changes. For example, WM appears relatively stable under hot working conditions or with extended work periods. In all cases, however, it has become clear that we cannot separate the underlying effects on cognitive processes from those relating to changes in performance goals or strategies. An increase in reliance on one kind of process may be the result of a strategic reduction in the use of another. Because of this, patterns of stressor effects cannot be discussed without reference to an understanding of what the performer is trying to do when carrying out a task and of what conflicts exist between different goals.

Compensatory Control under Stress

Modern treatments of psychological stress emphasize the cognitive transactions that mediate between stressful events and the adaptive response to them. This appraisal process evaluates the implications of the stressor for both current activities and personal

well-being. In terms of performance tasks, this may mean focusing information processing resources more strongly on the task (performance protection) or withdrawing resources in order to combat the stressor itself. This latter reaction is likely to be more effective in reducing the effects on bodily or emotional states, but it inevitably leads to a loss of performance goals. Performance protection is the usual response in everyday situations in which the individual is highly skilled, the task sufficiently important, and the stressor familiar and manageable. Serious disruption is rare for high-priority activities and is usually associated with traumatic events. This is because a compensatory process operates to maintain the primary task goals under the increased threat of disruption, resulting in a reduced response to the control of the emotional state and other competing goals. The increased effort underlying compensatory control is considered to reflect the involvement of the central executive functions responsible for the maintenance of high-level cognitive behavior, as observed in problem solving, reasoning, and all goal maintenance activity. As such, it is a limited resource that inevitably attracts costs when it is overemployed.

On the other hand, we know that decrements are relatively common, especially in laboratory studies or where skill and motivation are low. Within this framework, the specific patterns of decrement outlined earlier may be considered a baseline or default pattern of decrement under different stressors – how performance might be expected to suffer in the absence of compensatory control activity. As an example, consider a pair of studies carried out in Stockholm in the 1980s. They showed that noise impaired performance on an arithmetic task on one occasion but not on another. How can this be understood? The answer is related to motivational factors such as compensatory effort. The investigators also measured the physiological and subjective costs associated with having to work on the task under noise. In the study in which performance was unimpaired, they observed a marked increase in adrenaline and ratings of subjective effort. However, in the case in which performance was disrupted by noise, no such changes were observed. The most satisfactory explanation of this (and other similar) findings is that noise imposes an additional load on our capacity to maintain adequate orientation toward the task. If we can make an additional effort under such circumstances, performance may be protected against disruption, although only at the cost of increased strain in other areas. Alternatively, we may be unwilling (or unable) to make such an effort, in which case we will experience less strain but inevitably suffer a decrement in task performance. Such trade-offs are the routine consequences of having to manage stress

and other environmental demands while still carrying out our commitments to external task goals.

Latent Degradation under Stress

Although stress does not always result in any obvious reduction in performance, this should not be taken to mean that there is no threat to task goals. There is now considerable evidence of knock-on effects of performance protection to secondary aspects of behavior, related to both performance and costs; I have referred to these as latent degradation. By reducing the safe working margins of the adaptive control process, these may threaten the integrity of performance – for example, strategies that work only if there are no new problems to deal with. Four kinds of latent degradation may be identified: two performance indices (secondary task decrements and strategy changes) and two cost indices (psychophysiological activation and fatigue aftereffects).

Secondary Task Decrements

Decrements in the secondary aspects of performance are commonly observed in studies of the effects of high workload, providing an indirect measure of increasing load on primary tasks. Such effects have been studied less systematically in assessing threats from environmental stressors, although they are, in fact, also common. One of the best-documented forms of secondary task decrement under stress is the narrowing of attention found in spatially complex tasks. For example, although a central tracking task may be carried out effectively under noise, the detection of signals in the visual peripheral may be impaired. Similar attentional narrowing has been found under both laboratory and field conditions and for a wide range of environmental conditions (noise, heat, anxiety associated with deep sea diving, and threat of shock). This type of decrement may be related to strategy changes because they depend on a shift of priority between task elements.

Strategy Changes

Strategy changes are (usually adaptive) changes in the way that tasks are carried out under stress. One obvious way is to minimize the disruption to primary activities by reducing the time spent on secondary tasks. However, there may also be more subtle changes, involving a shift to less resource-intensive modes of task control, reducing dependency on effort-demanding processes such as WM, which is known to be impaired under stress conditions. Despite their obvious diagnostic value, such effects have not been well studied, partly because of the complex task environments

necessary to analyze strategy changes. It has been known for some time that, under periods of difficulty or stress, industrial process operators may shift from an attention-demanding open-loop control (in which whole sequences of actions are guided mainly by the operator's internal mental model) to a simpler closed-loop strategy (in which actions are carried out one at a time, paying more attention to feedback). This may slow the process or fail to make optimal use of available options, but it minimizes the likelihood of serious errors.

A good example of this is a well-known study of French air-traffic controllers, carried out in the 1970s. The controllers adopted a simplified method of dealing with aircraft contacts when they exceeded a comfortable number, but under very high workload they switched from individual plane-by-plane routing instructions to a fixed procedure for all contacts. By minimizing the demands for planning and aircraft management, they reduced the need to involve the vulnerable WM system. The strategy change is adaptive in that secondary goals such as airport schedules and passenger comfort are compromised in the service of the primary goal of safety. A second example is the work of Schönplug's group in Berlin, which used a simulated office environment to examine decision making in stock control. Under normal conditions, participants typically held background information (on prices, stock levels, etc.) in WM while making a sequence of decisions. However, under time pressure or loud noise, they tended to check lists containing such information before making each decision. Reducing the load on WM helped people to keep decision errors to a minimum, although at the expense of increased time costs. Again, the change is adaptive because accuracy matters more than speed in such work. However, in situations in which speed is also important, the hidden loss of efficiency represents a genuine stress-induced impairment.

Psychophysiological Activation

One of the most reliable costs of the use of increased effort to protect performance is the observation of increased levels of activation. This is particularly true of the physiological systems involved in emergency reactions (e.g., sympathetic and musculoskeletal responses, and responses of the neuroendocrine stress systems). These effects are typically accompanied by changes in subjective reports of emotional and mood states reflecting the affective response to emergency and sustained coping effort. These may be thought of as the unwanted side-effects of the compensatory behavior that helps to maintain

primary performance under threat from environmental conditions.

The effect is illustrated in an early study of sleep deprivation, in which decrements in arithmetic computation following a night without sleep were smaller for participants found to have increased muscle tension (interpreted as evidence of greater effort to combat sleepiness and maintain orientation toward the task). This performance-cost trade-off is seen more clearly in several studies of noise effects using more meaningful psychophysiological measures. Noise has been shown to increase heart rate, blood pressure, adrenaline, and subjective effort in tasks in which performance decrement is forestalled. In the Swedish study referred to earlier, two different patterns of arithmetic performance and costs were observed in different experiments. In one, performance was impaired by noise, with no change in levels of adrenaline or effort. In the other, performance was maintained, but adrenaline and effort levels were both greater. Unfortunately, because of the difficulty of obtaining psychophysiological measures under such circumstances, there are few studies within real work contexts, although another Swedish study found that the absence of decrement in work output during an intense period of organizational change was, again, accompanied by a compensatory increase in adrenaline and cognitive effort.

Such effects illustrate the role of compensatory regulation in the protection of performance and may be seen as a trade-off between the protection of the primary performance goal and the level of mental effort that has to be invested in the task. They also indicate that the regulation of effort is at least partially under the control of the individual rather than being an automatic feature of task or environmental conditions.

Fatigue Aftereffects of Stress

A final form of latent degradation is one that appears only after set tasks have been completed, in terms of decrements on new (and less critical) tasks. Such after-effects have also been studied very little, and then normally within a workload-fatigue paradigm. However, they are equally appropriate as a response to the sustained effort required to maintain effective levels of work under stressful environmental conditions.

Given its long-recognized importance, work fatigue has been studied extensively since the early days of psychology, although it has proved surprisingly difficult to demonstrate carry-over effects of this kind. Even intensive research programs carried out by the U.S. army failed to find any marked fatigue effects of periods of up to 60 h of continuous work. Holding

and others have showed that there are methodological difficulties in the analysis of this apparently straightforward problem. As with the compensatory response to stressors, participants in such experiments appear able to work harder (make more effort) for brief periods to respond to the challenge of any new test, effectively compensating for any reduction in capacity. However, when tired people are provided with alternative ways of carrying out the postwork test they are more likely to choose one requiring low effort, even though it entails more risk of error. Similar results of high workload and stressful jobs have been found for driving examiners, bus drivers, and junior doctors. This approach to fatigue reveals it to be a state in which there is a shift toward preferring activities requiring less effort or use of WM. So far, there has been little direct research on this form of decrement with laboratory stressors, although similar effects have been found for noise and high workload.

The link between stress and fatigue is a very strong one. It is likely that actively managing stress in order to protect performance leads directly to fatigue, so that recovery is necessary before we can function even when the stressor is no longer present. Recent work carried out in the Netherlands suggests that fatigue impairs the effectiveness of the executive control system that maintains the activation of tasks in working memory, triggering both the withdrawal of effort and compensatory changes in information processing strategy. At present, we have no direct evidence of the

brain processes involved in this stressor → control/effort → fatigue chain, but it is currently being addressed in a number of laboratories. Clearly, a better understanding of the physiological basis of the control of stress during task performance will help us manage work and other tasks more effectively, as well as informing our approach to the design and management of the working environment.

Epilepsy and Seizures
Stress and Seizures
Epilepsy as a Stressor
Interventions

Glossary

Electroencephalogram (EEG)
Epilepsy

A study of the electrical activity of the brain.

A condition characterized by recurrent (two or more) unprovoked seizures.

Epileptic seizure

An abnormal electrical discharge of brain neurons that results in a transient alteration in a person's normal level of consciousness and/or motor, sensory, autonomic, or psychic functioning.

Non-epileptic seizure-like event (NESLE)

An episode that behaviorally resembles an epileptic seizure but that is not associated with epileptic activity on EEG monitoring.

Provoked seizure

A seizure caused by and occurring in close temporal association with nonepileptic conditions such as metabolic abnormalities, infections, intoxications (e.g., from alcohol and illicit drugs), brain injury,

sleep deprivation, and various emotional states and experienced typically as an isolated event.

Epilepsy and Seizures

Patients with epilepsy frequently report that stress and stressful life events influence the frequency and severity of their seizures and that epilepsy itself can cause significant stress. A survey of more than 1500 patients with epilepsy that was completed in 2005 indicated that emotional stress, sleep deprivation, and tiredness were the most frequently reported precipitants of seizures. Another survey, completed in 2003, found that 64% of patients believe stress increased seizure frequency and that 32% had specifically tried stress-reducing techniques to help with their epilepsy. Despite the apparent relationship between stress and epilepsy, there is a relatively poor understanding of the specific means by which stress affects the occurrence of seizures. Clinical studies have provided strong anecdotal information and evidence of stress-related seizure activity, but these studies are relatively few and inconclusive. Basic science research has delineated many of the relevant anatomical pathways of the brain and the potential physiological mechanisms that could be affected by stress, including how changing concentrations of various hormones and neurotransmitters can affect seizure threshold. However, the information from these studies remains incomplete and further research is necessary. Despite the lack of specific knowledge about the complex interplay between stressful stimuli and the seizures that apparently occur in response to them, some basic understanding of these relationships does exist.

To facilitate an understanding of how stress can influence the occurrence of seizures, a description of the various types of epilepsy and the seizures that characterize them is important. Epilepsy is classified as of unknown cause (idiopathic, primary), of known cause (symptomatic, secondary), or of unknown cause but presumed to be symptomatic (cryptogenic). Idiopathic epilepsy is considered to have a hereditary cause (e.g., childhood and juvenile absence epilepsy and juvenile myoclonic epilepsy), whereas symptomatic epilepsy is considered to be a consequence of a known or suspected brain injury (e.g., perinatal hypoxia, meningitis, and trauma). The different types of epilepsy are characterized by a variety of seizure types that are classified as either partial (clinical or EEG evidence that indicates a focal onset in one cerebral hemisphere) or generalized (no evidence of focal onset, thus appearing to begin simultaneously in both cerebral hemispheres).

Partial seizures are described as simple (without impairment of consciousness) or complex (with impairment of consciousness). Simple partial seizures can include the following types of symptoms: motor (jerking of an arm), sensory (numbness, tingling, autonomic (piloerection, pupillary dilatation), and psychic (deja vu, fear, structured hallucinations). Simple partial seizures are typically associated with an abnormal electrical discharge in a restricted area of the contralateral cerebral cortex corresponding to the body area involved. Aura has been used traditionally to describe the sensory, autonomic, or psychic symptoms perceived by the patient before the onset of impaired consciousness and/or a motor seizure. Actually, an aura is a simple partial seizure that may or may not progress to another seizure type. Prodromal symptoms of prolonged mood changes, uneasiness, or premonitions are usually not auras. A simple partial seizure may progress to a complex partial seizure, which also can occur spontaneously. A complex partial seizure includes impairment of consciousness, which refers to the patient's abnormal awareness of and responsiveness to environmental stimuli. The initial features of the seizure include an arrest reaction or motionless stare usually followed by automatisms, which are relatively coordinated motor activities occurring during the period of impaired consciousness (lip smacking, fumbling with clothing). The seizure is usually brief, lasting from seconds to minutes, and there is a period of postictal (after the seizure) confusion. These seizures are often referred to as temporal lobe seizures or psychomotor seizures. A partial seizure, simple or complex, can evolve into a generalized tonic-clonic seizure. The EEG shows focal discharges in one cerebral hemisphere evolving into generalized, bilaterally synchronous discharges.

Generalized seizures are divided into convulsive (major motor) or nonconvulsive (brief loss of consciousness or minor motor) types. Generalized convulsive seizures include tonic, clonic, and tonic-clonic types. Generalized tonic seizures usually occur in childhood and typically include impaired consciousness, muscle contraction of the face and trunk, flexion of the upper extremities, flexion or extension of the lower extremities, and postictal confusion. Generalized clonic seizures usually begin in childhood and include impaired consciousness, bilateral limb jerking, and postictal confusion. Generalized tonic-clonic seizures, commonly referred to as grand mal seizures, are characterized by a sudden loss of consciousness and tonic and clonic phases. Following this, there is muscular flaccidity and there may be incontinence. Consciousness returns gradually and the patient awakens in a confused state. Fatigue and headache are common. The EEG shows abnormal synchronized discharges

from both cerebral hemispheres in the tonic and clonic phases and diffuse slowing in the postictal period. Generalized nonconvulsive seizures include absence, myoclonic, and atonic types. Generalized absence seizures, commonly referred to as petit mal seizures, typically are 5- to 10-s episodes of impaired consciousness characterized by staring and unresponsiveness. Clonic movements, changes in postural tone, automatisms, and autonomic phenomena frequently accompany absence seizures. The patient quickly resumes normal consciousness, has no postictal confusion, and is generally unaware of the episode. Generalized myoclonic seizures are bilaterally synchronous jerks that can be single or repeated in trains. The muscles involved may be few and restricted to a body part (e.g., face) or extensive, involving all limbs. Most myoclonic seizures occur with no impairment of consciousness. Generalized atonic seizures, commonly referred to as drop attacks, consist of a sudden loss of tone in postural muscles often resulting in a fall. There is brief, mild impairment of consciousness and little postictal confusion.

When partial or generalized seizures represent a chronic condition and have no identifiable cause or a cause that cannot be cured by specific treatment, the seizure is caused by epilepsy. This distinguishes partial or generalized provoked seizures, which are not caused by epilepsy but by transient reversible causes (e.g., low blood sugar) or by conditions that can be cured by definitive therapy of an underlying disease state (e.g., removal of a brain tumor). Provoked seizures are usually isolated events but can be recurrent. There are many diverse causes of provoked seizures, including metabolic disorders (uremia, liver failure, and hypoglycemia), electrolyte disorders (hyponatremia and hypocalcemia), acid-base disorders, connective tissue and inflammatory disorders (systemic lupus erythematosus, rheumatic fever, and vasculitis), endocrine disorders, infections (meningitis and encephalitis), vascular disorders (transient ischemic attack and stroke), toxic disorders (medications, substances of abuse, and environmental toxins), head trauma, and pregnancy (eclampsia). It is important to distinguish provoked seizures from epileptic seizures because treatment of the underlying cause of provoked seizures will usually prevent further seizure occurrence, thereby obviating the need to treat the seizures with medication.

Stress and Seizures

Stress can be thought of as a diverse set of stimuli or conditions, intrinsic or extrinsic, that can perturb the physiological state of an organism. Categories of stressors include physiological (sleep deprivation,

hyperventilation, overexertion, dehydration, fever, illness, and menstrual cycle), pharmacological (medications and substances of abuse), environmental (extremes of temperature, noise, lighting, and smells), and psychological (situations resulting in fear, sadness, and anger). These stressors, alone or in combination, can alter the homeostatic mechanisms maintaining a normal physiological state, lower the seizure threshold, and result in the occurrence of a seizure. The specific means by which stress precipitates a seizure is not known. The subjective intensity of a stressor frequently does not necessarily correlate with the likelihood of seizure occurrence. Similarly, the temporal onset of a stressor(s) is often difficult to determine, and the latency-to-seizure occurrence is frequently variable. However, in many circumstances, a specific stressor can be identified and its intensity and temporal relationship to the seizure strongly suggest a direct relationship. A recent study in Croatia found that children with epilepsy in a war-affected area had more seizures than children in a non-war-affected area.

Some patients with well-controlled epileptic seizures experience an unexpected seizure after an unusual event has altered their typical routines and activities. Sleep deprivation is frequently the only identified change in a patient's routine that is associated with a breakthrough seizure; patients report having had little or no sleep the night before a seizure has occurred. This may have been due to simply going to bed later than usual, studying late for an exam, or awakening earlier than usual in the morning for an appointment. Often these circumstances can include other potential stressors such as caffeine, alcohol, and anxiety, which compound the clinical identification of only one stressor associated with the seizure occurrence. Hyperventilation, the increased frequency or depth of respirations, can be a reaction to stress and is used as a standard procedure in most routine EEGs to determine whether some forms of seizure activity can be induced. For example, generalized absence seizures and, less commonly, complex partial seizures at times can be easily precipitated with hyperventilation. Vigorous physical activity is usually associated with hyperventilation and can be the setting in which an unexpected seizure occurs. Seizures often occur during illness when fever and dehydration may be present. Correspondingly, overexertion with dehydration and the elevation of core body temperature can also be associated with seizure occurrence.

In addition to these circumstances that are unusual for the patient's day-to-day experience, certain physiological changes occur cyclically and may be related to seizure occurrence. The hormonal fluctuations of the menstrual cycle can contribute to seizure break-

through in susceptible women at the time of ovulation, perimenstrually, and throughout the luteal phase of the menstrual cycle (the time between ovulation and menstruation). Animal studies that assess gender-based differences in the association of stress and seizure risk (e.g., those of Chadda and Devaud) support the concept that the relationship between stress and seizure risk may be different in men and women. Pharmacological stressors associated with seizures in patients are often prescribed or over-the-counter medications. The seizures may be idiosyncratic or a result of an interaction with the metabolism of antiepileptic or other drugs that the patient takes chronically. As mentioned earlier, common substances such as caffeine and ethanol can be associated with seizure occurrence, as can other substances such as cocaine, amphetamines, and withdrawal from barbiturates or benzodiazepines.

Environmental stressors are at times difficult to identify, but an increased level of subjective stress can be associated with extremes of temperature, persistent and offending noises, lighting that can cause glare and subsequent headache, and particularly offensive smells. These situations are distinguished from reflex epilepsy, which is characterized by seizures evoked by specific stimuli and usually time-locked with the stimulus, such as in stroboscopic illumination. Psychological stressors, such as sudden anger, marked fear, and unexpected mourning, can result acutely in the occurrence of seizures. More chronic psychological factors, such as depression, anxiety, or hypomania, may fluctuate in intensity and predispose an individual to seizure occurrence.

The nature of stress-related seizures is such that attempts to study the relationship of a stressor and potential changes in the electrical brain activity of patients are very difficult. Although standard activating procedures such as photic stimulation and hyperventilation are used in routine EEG studies to precipitate ictal discharges and clinical events, the relationship of other stressors to seizure occurrence cannot be studied in this fashion. Patients undergoing evaluation for epilepsy surgery can be studied with a variety of electrode types, sometimes indwelling in the brain, and electrical and clinical seizures are monitored in a more comprehensive way. However, even in these very structured settings, the common stressors that have been discussed are not easily evaluated. The difficulty of quantifying the relationships between stress severity and latency to seizure onset is no less in these settings than it is in a typical clinical situation.

Basic science research into the functional anatomy of the brain involved in stress and seizure activity includes the amygdala, hippocampus, frontal cortex,

and dorsal raphe nucleus. These same brain structures are known to be involved in the propagation of electrical seizure activity in both animal models and in humans. Many studies have focused on the effects of hormones and neurotransmitters, including corticotropin releasing hormone (CRH), catecholamines, and serotonin, many of which can have effects on seizure threshold. Although a growing body of evidence implicates these neuromodulators or neurotransmitters as being involved in the expression of stress-related seizures, their precise mechanisms of action are not fully elaborated and clear clinical confirmation of their effects are not easily obtained. For example, in Klein and Sahoo's pilot study of patients with partial seizures and subjectively perceived stress-related seizures, the injection of adrenocorticotrophic hormone (ACTH) induced hypercortisolemia in all patients (cortisol is known to promote seizure activity in animal models), but was not associated with increases in interictal spike discharges on EEG or seizures in any patient. Despite the experimental difficulties inherent in this field of study, numerous studies are ongoing that will undoubtedly increase the knowledge base in both basic science and clinical areas.

Epilepsy as a Stressor

People with epilepsy frequently are faced with limitations in educational and employment opportunities, they may be restricted or prevented from driving, and they may regularly confront societal prejudices against them. Even well-meaning family members, friends, and coworkers may alter how they behave toward the person with epilepsy after witnessing a seizure or learning of this diagnosis. Feelings of loss of control are common, particularly for the patient with seizures that are incompletely controlled by medications. The high cost of medical care combined with limited employment opportunities increases the risk of financial hardship, which can increase life stress. In addition, epilepsy may be accompanied by cognitive deficits, decreased interpersonal skills, and psychiatric problems, which can cause increased stress in an individual's life and result in decreased resources for coping with life stress. All this probably contributes to the finding in a 2003 study that people with epilepsy have an average rate of suicide as high as 12%, compared to less than 1.5% in the general population.

NESLEs, or pseudoseizures, are generally understood to be psychological or psychiatric in origin rather than physiological. Suggested causes include affective and anxiety disturbances, panic disorder, posttraumatic stress disorder, conversion disorder, dissociative disorder, factitious disorder, psychosis, malingering,

hypochondriasis, and somatoform disorder. NESLEs are not uncommon, with as many as 400 000 individuals in the United States at risk for developing them in their lifetime. Many patients with epilepsy will also experience NESLEs, which can make the diagnosis even more challenging. Differentiating NESLEs from epileptic seizures is frequently performed by a multidisciplinary team in epileptology with expertise in neurology, neuropsychology, psychiatry, and nursing. Video-EEG monitoring can demonstrate that some behavioral events do not have an associated ictal discharge on the EEG and are often consistent with the diagnosis of NESLEs.

Interventions

Epileptic seizures are usually treated with antiepileptic drugs (AEDs). An AED is chosen based on the patient's type of epilepsy and/or seizure(s). Several of the available AEDs are effective in treating both partial and generalized seizures; however, most AEDs have specific indications for use and may be ineffective in the treatment of particular seizure types. An AED may be prescribed as monotherapy when it is effective in controlling seizures. When one AED is inadequate in controlling seizures, combinations of AEDs (polytherapy) are used. AEDs used commonly in the treatment of partial seizures include phenytoin, carbamazepine, lamotrigine, topiramate, oxcarbazepine, levetiracetam, and zonisamide; phenobarbital and valproic acid are also used for the treatment of partial seizures. Convulsive generalized seizures are treated with phenytoin, phenobarbital, valproic acid, and benzodiazepines. Nonconvulsive generalized seizures are treated with valproic acid and ethosuximide. The treatment of generalized seizure disorders will often include many of the AEDs used for treatment of partial seizures.

When seizure disorders are inadequately controlled with the use of AEDs, epilepsy surgery and the vagus nerve stimulator (VNS) may be used. Epilepsy surgery is performed for some seizure disorders, typically when the seizures have a focal onset in an area of the brain determined to be safe for surgical intervention. The VNS is a device implanted in the chest and connected to the vagus nerve by a wire; it is designed to deliver current pulses at specific intervals to decrease the likelihood of seizure onset. Patients can also activate the device to deliver a current pulse when they recognize the onset of a seizure in an attempt to abort or lessen the severity of the seizure. The VNS is programmed by the patient's epileptologist and adjusted as required by the frequency and severity of the seizures.

Helping patients cope with life stress and the stress that results from having epilepsy may decrease the likelihood of seizures and enhance quality of life. Multiple treatment modalities can be effective for managing stress, including progressive relaxation, biofeedback, and meditation. However, this relationship may be more complicated than merely working to reduce stress and more research on which treatments are most helpful clearly needs to be done. For example, Jaseja suggested that meditation may result in brain changes that can increase the risk of developing epilepsy and the severity and frequency of attacks. This is in conflict with the results of other studies with various behavioral therapies that suggest that these therapies can reduce seizure frequency and/or increase satisfaction with other aspects of life. In addition, one study demonstrated that patients, particularly those who were described as highly reactive to stress, were able to reduce seizure frequency using a behavioral self-management program that taught self-regulation of slow cortical potentials. Patients may also benefit from cognitive behavioral therapy, which encourages them to alter their thinking and behaviors that may be contributing to anxiety, depression, and feeling overwhelmed. Interpersonal psychotherapy and assertiveness training can assist patients in learning how to interact in healthier ways with family members, coworkers, and peers and may positively impact levels of perceived stress. Medication for psychiatric problems can result in better control of anxiety and of affective and thought disorder symptoms and thus reduce life stress. A recent study found that the antidepressant fluoxetine reduced seizures in mice that were and were not exposed to stressful conditions. For patients with specific problems related to hyperventilation, relaxation training may be helpful. Patients with sleep disturbances may benefit from learning basic sleep hygiene, increasing activity levels, and treating anxiety and affective disorders that may be disrupting sleep. Gupta's study suggested that training that specifically addresses cognitive deficits in patients with epilepsy can be helpful in improving cognitive performance, which may in turn reduce life stress. Support groups, family therapy, psychoeducation, and supportive psychotherapy are beneficial for patients coping with epilepsy and the daily challenges and difficulties that attend it. Encouraging patients to make use of special programs and organizations specifically developed to assist people with epilepsy (e.g., the Epilepsy Foundation) can be helpful.

The treatment of patients with NESLE is determined by the suspected cause. Patients frequently are found to have problems with depression, anxiety,

or thought disorders, and treatment with antidepressants, anxiolytics, or antipsychotic medication, as well as psychotherapeutic and behavioral intervention, may be useful. Psychological and personality testing, combined with an evaluation of environmental factors that may be contributing to this disorder, contribute in formulating appropriate intervention strategies. For patients with both epileptic seizures and NESLEs, different strategies may be suggested for treating the seizures and the NESLEs. Identifying stressors that may be precipitating or maintaining the NESLEs may be particularly effective in reducing both the frequency and the impact of these events on the patients' lives.

Axis

Sex Differences in the Stress Response: The Effects of
Estrogen on Cognitive Function

Implications for Health

Glossary

<i>Amenorrhea</i>	The absence of menses.
<i>Endothelium</i>	The innermost layer of blood vessels; made up of squamous epithelial cells.
<i>Genomic mechanisms</i>	Mechanisms involving the regulation of gene expression.
<i>Gonadotropins</i>	The pituitary hormones that stimulate the ovaries and testes (i.e., luteinizing hormone and follicle stimulating hormone).
<i>Gonadotropin releasing hormone</i>	A hormone secreted by the hypothalamus that acts on the pituitary to control the secretion of the gonadotropins.
<i>High-density lipoprotein (HDL) cholesterol</i>	A lipoprotein cholesterol complex that transports cholesterol from cells in peripheral tissues to the liver for excretion from the body.
<i>Low-density lipoprotein (LDL) cholesterol</i>	A lipoprotein cholesterol complex that delivers cholesterol to cells in peripheral tissues in order to support metabolic and structural needs.

Estrogen is a class of steroid hormones produced mainly by the ovaries. It is often referred to as the

female sex hormone; however, this is a misnomer because estrogen is also found in males, albeit in much smaller amounts than in females. In premenopausal women, the most common and potent form of estrogen is estradiol, followed by estrone and estriol. Estradiol secretion rates vary according to the phases of the menstrual cycle; it is, 0.07 mg day⁻¹ in the early follicular phase, 0.6 mg day⁻¹ preceding ovulation, and 0.25 mg day⁻¹ during the middle of the luteal phase. In men, the estradiol production rate is approximately 0.05 mg day⁻¹. Estrogens have numerous well-documented effects on the female reproductive system. They facilitate the growth of the ovarian follicles, increase the motility of the uterine tubes, maintain the cyclic changes of the uterus, stimulate ductal growth in the breasts, inhibit the secretion of follicle stimulating hormone, and play a major role in the development of female secondary sex characteristics. Estrogens exert the majority of their effects via intracellular receptors that bind to DNA; however, recently it has been shown that estrogens may also act through nongenomic mechanisms (e.g., alterations in cell membrane permeability).

The Stress Response: Sympathetic Nervous System and the Hypothalamic-Pituitary-Adrenocortical Axis

In addition to their well-known effects on the reproductive system, estrogens interact with the two major systems involved in the stress response – the sympathetic nervous system and the hypothalamic-pituitary-adrenocortical (HPA) axis. The activation of the sympathetic nervous system results in the release of noradrenaline from the various organ systems it innervates, with the exception of the adrenal medulla, which releases adrenaline. The release of noradrenaline and adrenaline causes a number of bodily changes including an increase in heart rate and blood pressure and a rise in serum cholesterol and free-fatty acid levels. With regards to the HPA axis, when a stressor is encountered, corticotropin releasing hormone

(CRH) is secreted from the hypothalamus. CRH stimulates the pituitary to release adrenocorticotrophic hormone (ACTH), and, in turn, ACTH stimulates the adrenal gland to release glucocorticoids. Cortisol is the main glucocorticoid in humans, whereas corticosterone is the main glucocorticoid in rodents. Approximately 95% of circulating glucocorticoids are bound to corticosteroid-binding globulin (CBG), a protein synthesized by the liver. The unbound 5% constitutes the biologically active portion of glucocorticoids.

Estrogen and the Sympathetic Nervous System

There is a significant body of animal studies and, to a lesser extent, human studies demonstrating that estrogens affect sympathetic activity. Animal studies suggest that estrogens decrease β receptor sensitivity to catecholamines and may diminish the secretion of epinephrine from the adrenal medulla. Estrogens modify α receptor sensitivity and noradrenergic synthesizing and degrading enzymes. In both animal and human studies, estrogens have been found to affect cardiovascular activity. For example, estrogens increase blood flow by increasing vasodilation. How this is achieved is at present unclear; however, a number of possible mechanisms exist. Estradiol may enhance endothelium-dependent and -independent relaxation, and it may have a direct effect on the vascular smooth muscle. Estrogens may also affect cardiac function. Estradiol receptors have been found in the rat heart and estradiol has been found to affect both heart rate and contractility. Estrogens also affect cholesterol levels. Following menopause, women's estradiol levels are low and a decrease in HDL cholesterol and an increase in LDL cholesterol levels are observed. Moreover, estrogen replacement in postmenopausal women has been found to partially reverse these changes in cholesterol levels.

The effects of estrogens on cardiovascular, noradrenergic, and lipid responses to stress are at present unclear. To date, only a few studies have examined this relation. On the one hand, endogenous estrogen levels have been found to be negatively related to heart rate, cardiac output, and systolic blood pressure responses to stress in healthy premenopausal women. On the other hand, exogenous estrogens have been found to either decrease or have no effect on postmenopausal women's cardiovascular responses to stress and to increase premenopausal women's cardiovascular responses to stress. Similarly, estrogens have been found to increase, decrease, or have no effect on adrenaline responses to stress in humans. The equivocal results may be due to the type of estrogen used and

the method of administration. For example, some studies have used only estradiol, whereas other studies have used preparations containing estradiol and other estrogens. There is evidence that estradiol may have different physiological effects when compared to other types of estrogens. Also, transdermally applied estradiol may be more likely to cause a decrease in blood pressure than orally administered estrogens, although recent research has found decreases following oral administration. Increased plasma levels of an oxytocin intermediate peptide (oxytocin-glycine), resulting from oral estrogen replacement in postmenopausal women, has been linked to reduced blood pressure and vascular resistance during a speech stressor task. Acute transdermal estrogen administration to healthy postmenopausal women, however, had no statistically significant differential effects on heart rate, blood pressure, or noradrenaline spillover, during a mental stressor (Stroop test) or physical stressor (cold pressor) task.

The effect of estrogens on lipid responses to stress has been directly and indirectly examined in only a few studies. For example, there is evidence that estrogen administration attenuates free fatty acid and glycerol responses to stress. Also, women who have undergone a surgical menopause have been found to exhibit greater LDL cholesterol responses to stress than women with intact ovaries.

Estrogen and the Hypothalamic-Pituitary-Adrenocortical Axis

There is a bidirectional relation between the HPA axis and the reproductive system. The activation of the HPA axis inhibits the functioning of the hypothalamic-pituitary-gonadal axis in mammals, and there is some evidence for this effect in humans as well. Glucocorticoids have been found to inhibit the secretion of gonadotropin releasing hormone and the gonadotropins, which leads to a decrease in estrogen synthesis. Glucocorticoids also inhibit estradiol-stimulated uterine growth. In turn, there is evidence from animal studies that estrogens affect HPA axis function.

In rats, estrogen administration increases baseline corticosterone and ACTH secretions and corticosterone and ACTH responses to stress. Furthermore, corticosterone and ACTH levels are at their peak during proestrus, when circulating levels of estrogen are high. Immobilization stress during a 2-h period has been shown to result in an elevation in plasma ACTH in non-estradiol-treated rats and a lesser elevation in estradiol-treated rats. In this study, blood pressure remained elevated during the 2-h period in the control group; however, the elevation was reduced after 70 min in the treated rats. Other stress

responses were either unaffected, for example, an equivalent rise in tyrosine hydroxylase mRNA in both the adrenal medulla and the nucleus of the solitary tract of the control and treated rats, or reversed, for example, a decrease in the dopamine β -hydroxylase mRNA levels in the locus coeruleus. The administration of diethylstilbestrol to ovariectomized rats suppressed c-Fos accumulation in prolactin-releasing peptide, producing A2 noradrenergic neurons, while the rats were in a restraint stress condition. These A2 neurons located in the medulla oblongata are known to mediate the stress response.

In humans, the effects of estrogens on the HPA axis response to stress are less clear. Only a few studies have been conducted. Although estrogen administration has been found to increase cortisol levels in most studies, this has not been a uniform finding. Estrogens affect the HPA axis at multiple levels. Estrogens increase HPA axis activity by modulating corticosterone negative feedback in the hippocampus, binding to CRH cells in the hypothalamus, increasing the secretion of corticosterone by the adrenals, and increasing anterior pituitary sensitivity to CRH. Estrogens also stimulate the production of CBG by the liver. With higher levels of CBG, more glucocorticoids must be secreted in order to maintain the same amount of glucocorticoids in the unbound biologically active state. Thus, this may account for the higher levels of circulating glucocorticoids in females. Sex differences in HPA axis function may be the result of both central differences and adrenal sensitivity to ACTH. Kajantie and Phillips have proposed a framework to explain the discrepancies found with regard to estrogen and its role in the psychosocial stress response. Attenuation may be the result of a decrease in arginine vasopressin (AVP) mediated by estrogen β receptors and an increase in CRH mediated by estrogen α receptors.

Sex Differences in the Stress Response: The Effects of Estrogen on Cognitive Function

Stress has been shown to have effects on both animal and human cognitive functioning, with sex differences being reported. Restraint-stressed female rats showed improved spatial memory; however, male rats showed small impairments. Estrogen may not only moderate the HPA axis and alter corticosterone release, it may counteract the effects of corticosterone. Given the lower level of estrogen in males, they may be more negatively impacted by high levels of stress-induced corticosterone.

Findings related to spatial learning and memory in nonstressed rats have been controversial, and recently researchers reported that physiological levels of estra-

diol did not appear to have any effect and that, at higher levels, performance impairments have been observed. Similar impairment has been found with tasks that depend on reference memory. Hippocampal neurons that are sensitive to estrogen(s) may play a role in influencing estrogen-level-mediated task-solving cognitive strategies in female rats. There is limited evidence that the circulating level of estradiol is an important component of sex differences in both the stress response and its impact on cognitive function. Stress-induced anxiety in ovariectomized rats has recently been shown to be attenuated following 17 β -estradiol replacement. Using a benzodiazepine inverse agonist (FG7142), which activates stress systems and typical stress responses including elevated corticosterone release, catecholamine turnover, heart rate, and blood pressure, researchers found that female rats were more sensitive to pharmacologically induced stress than male rats, but only under conditions of high estrogen, showing prefrontal cortex (PFC) impairment. This sex difference was also observed during mild levels of natural stress, with high-estrogen-level females showing PFC impairment. Behaviors consistent with reduced stress levels, such as social investigation by female rats, were shown to increase following long-term estrogen replacement, along with improved social recognition and reduced corticosterone stress response.

Implications for Health

The interaction of estrogens with the systems involved in the stress response has a number of implications for health. For example, it is well known that severe chronic stress interferes with the reproductive system and may cause amenorrhea. Estrogen is also known to protect women from cardiovascular disease, as evidenced by the increase in cardiovascular disease postmenopausally. Although it is known, for example, that the favorable effect of estrogens on resting cholesterol levels is one mechanism by which premenopausal women are protected, estrogen may also lower risk by decreasing the cardiovascular, noradrenergic, and lipid responses to stress. Estradiol's anti-inflammatory effects may act as a neuronal protector by moderating inflammatory factors and reducing the ability of inflammatory cells to enter the central nervous system (CNS). In addition, estrogens mitigate the effects of neuronal oxidative stress. Collectively, these CNS estrogenic effects are thought to play a protective role in several neurodegenerative pathologies, including Alzheimer's disease and Parkinson's disease.

Conversely, stress-induced lower levels of estrogen have recently been hypothesized to have a positive health effect. Higher levels of self-reported daily

stress were associated with a reduced risk of primary breast cancer, especially among women receiving hormone therapy. Overall, however, the chronic dysregulation of the stress system may have greater negative than positive health impact.

Recently, Kajantie and Phillips suggested that evolutionary forces led to a stress-response attenuation system that functions during pregnancy. Prenatal stress has been shown to have negative effects on the fetus, effects that have continued developmental sequelae. Estrogen, which rises during pregnancy to levels that are on the order of 100 times higher than peak nonpregnancy levels, clearly acts protectively through its effects on the autonomic nervous system. What is less clear is its effects on the HPA axis; however, during pregnancy AVP levels are low, which may attenuate the HPA axis response. During pregnancy AVP appears to have a greater role in regulating cortisol secretion than does CRH, which normally regulates cortisol. Further research in this area may help elucidate the recent findings related to the seemingly trimester-dependent effects of maternal prenatal stress and developmental sequelae.

Pharmacokinetics of Ethanol

Alcohol Reinforcement

Alcoholism

Alcohol Effects on the Developing Brain

Glossary

<i>Alcohol withdrawal syndrome</i>	Symptoms experienced by alcoholics when they stop drinking, including profound anxiety, body shakes, intense hyperactivity, sleep disturbances, hallucinations, and seizures.
<i>Alcoholism</i>	A disease that develops when a person loses control over his or her drinking of alcohol and develops tolerance for and dependence on it; also called alcohol dependence.
<i>Craving</i>	The hunger for alcohol before drinking begins.
<i>Impaired control over drinking</i>	The difficulty that an alcoholic experiences in stopping once his or her drinking has started.
<i>Physical dependence</i>	An adaptive state manifested by intense physical disturbances that occur when drinking is discontinued. Dependence necessitates continued drinking to relieve the discomfort of alcohol withdrawal syndrome. During withdrawal, some alcoholics experience only mild symptoms,

Ethanol is an organic chemical that belongs to the chemical class of alcohols; it is also called ethyl alcohol, grain alcohol, methyl carbinol, and ethyl hydrate. The molecular formula of ethanol is C_2H_6O . Ethanol is used as a food, a drug, and in the manufacture of industrial and consumer products. The use of alcohol as a beverage at social events and festivals dates back to the ancient Egyptian, Mesopotamian, Greek, and Roman civilizations. Moderate alcohol use, up to two drinks per day for men and one drink per day for non-pregnant women and older people, is not harmful for most adults.

Pharmacokinetics of Ethanol

Ethanol is rapidly absorbed on ingestion; approximately 80–90% of ethanol is absorbed within 30–60 min, although food may delay the absorption for a longer period of time (4–6 h). Ethanol is both water- and lipid-soluble, easily penetrates the blood-brain barrier, and distributes into the brain and total body fluid. Approximately 90–98% of any consumed ethanol is oxidized by the liver, and 5–10% is excreted by the kidneys and lungs.

Ethanol can be a central nervous system (CNS) depressant. Mild ethanol intoxication (blood alcohol concentration, BAC, 0.05–0.15%) leads to the impairment of visual acuity, changes in mood and personality, decreased reaction time, and muscular incoordination. Severe ethanol intoxication (BAC 0.3–0.5%) exacerbates these problems and in addition brings about hypothermia, vomiting, nausea, hypoglycemia and convulsions, depressed reflexes, and death from

respiratory or circulatory failure. Alcohol consumption during pregnancy can lead to a congenital malformation of the offspring, which is known as fetal alcohol syndrome. Affected infants often show mental deficiency, microcephaly, and irritability.

Alcohol Reinforcement

Alcohol's basic action on the CNS causes pleasant subjective effects or a high feeling. This mild euphoria produced by alcohol often reinforces alcohol drinking. Alcohol also relieves anxiety from stressful life situations by reducing the aversive physiological stimuli associated with anxiety and stress. The reinforcing effects of alcohol involve chemical communication between various neuronal systems, including opiodergic neurons in the CNS.

Alcoholism

Alcoholism, or alcohol dependence, normally refers to when a person loses control over his or her alcohol drinking and develops a tolerance to and dependence on alcohol. Whereas moderate alcohol consumption may relieve stress and improve psychological well-being, alcohol dependence and depression are a prevalent combination of psychiatric disorders among patients seeking treatment. The highest psychiatric comorbidity for people with alcohol dependence appears to be affective anxiety and antisocial personality disorders.

Behavioral Aspects

The stress-relieving action of alcohol has been well documented in human subjects. This anxiolytic action of alcohol led to the belief that the motivation for abusing this substance may be prompted by individuals' needs to cope with (relieve) stress. Stress is often defined as a process involving the perception of, interpretation of, and response to harmful, threatening, and challenging events. Psychosocially, it is defined as tensions or challenges that an organism faces; physiologically, it is the biological responses upregulated by exposure to stressors. People often use drugs to enhance mood and alleviate emotional distress, and the motivation to enhance mood is great in acute and chronic stress states. There is a link between the maladaptive stress response and drug addiction in vulnerable individuals who are exposed to stress. The maladaptive stress response includes high or low reactivity and sensitivity to stress stimuli, a slow biological recovery after the initiation of stress, and poor cognitive and behavioral coping. Individuals at high risk for alcoholism show a heightened physiologi-

cal and subjective sensitivity to the stress-reducing effects of ethanol. In addition, genetic and individual vulnerability factors may influence the maladaptive stress response to increase the use of abusive substances. Clinical studies have suggested a link between genetically related risks for alcoholism and an alteration in the hypothalamic-pituitary-adrenal (HPA) axis. It has been shown that the capacity of the HPA axis to respond to stress is more labile in family-history-positive individuals, and this may promote their use of ethanol to relieve stress.

Biochemical Aspects

Endogenous opioid peptide mediation of ethanol action Opioid deficiency may be partly responsible for the maladaptive stress response that may promote alcohol abuse in vulnerable humans following stress. A slow biological recovery of the HPA axis after the initiation of stress may be explained by the opioid deficiency hypothesis. After the perception of stress, the neuronal input converges on the corticotropin releasing hormone (CRH) neurons. These neurons secrete CRH into hypophyseal portal circulation. CRH then enters the pituitary and acts primarily on corticotrophs (and melanotrophs) to stimulate the release of adrenocorticotrophic hormone (ACTH) and β -endorphin from the pituitary gland. ACTH acts on the adrenal gland to release glucocorticoids. When the glucocorticoids reach threshold levels, it prevents CRH secretion and brings about homeostasis. The CRH-producing neurons receive signals through three major neurotransmitter systems: stimulatory input from serotonergic-producing neurons and inhibitory inputs from gamma-aminobutyric acid (GABA) neurons and β -endorphin neurons. Because of the powerful inhibitory input of β -endorphin neurons on CRH release, an acquired or inborn abnormality in β -endorphin activity can be an important determinant of the magnitude of the stress response. More β -endorphin activity allows the constrained stress response, whereas less β -endorphin activity allows for a more labile stress response. If individuals at high risk for alcoholism have reduced functional β -endorphin neurons, these opioid differences may explain why these individuals show slow biological recovery after the initiation of stress.

Three major groups of endogenous opioid peptides have been isolated and characterized: the endorphins from the β -endorphin/ACTH precursor known as proopioidmelanocortin, the enkephalins from the pro-enkephalin precursor, and the dynorphins and neo-endorphins from the prodynorphin precursor. The 31-amino-acid peptide β -endorphin, with a reasonably high affinity for the mu and delta forms of the

opiate receptors, is present in high concentrations in the hypothalamus. The β -endorphin-producing perikarya are located mainly in the ventromedial arcuate nucleus region, which projects to widespread brain structures, including many areas of the hypothalamus and the limbic system, where this opioid peptide has been proposed to function as a neurotransmitter or neuromodulator regulating a variety of brain functions. These brain functions include psychomotor stimulation; positive reinforcement; adaptive processes; drinking, eating, and sexual behaviors; pituitary function; thermoregulation; nociception; and mood. It is generally believed that the endogenous opioid system mediates some of the reinforcing properties of ethanol. Neurobiological studies indicate that alcohol alters opioid peptide systems. Acute alcohol administration increases endorphin and enkephalin gene expression in discrete brain regions and increases the release of these peptides from the brain and pituitary in rodents. Chronic or binge alcohol administration decreases proopiomelanocortin gene expression and alters the diurnal rhythm of proopiomelanocortin gene expression, β -endorphin release, hypothalamic levels of β -endorphin, and opioid receptor affinity and binding. Opioid-receptor antagonists have been shown to decrease ethanol consumption. The extended amygdala is considered to be a site of the opioid action because a high proportion of cells in the medial nucleus of the amygdala and the bed nucleus of the stria terminalis express μ - and δ -opioid receptors. The extended amygdala is also a major brain area involved in excessive ethanol consumption.

The abnormal expression of opioid receptors in the brain is connected with the volitional ethanol consumption. μ -Opioid receptor densities have been shown to be higher in the extended amygdala in alcohol-preferring rat and mouse strains. Selective μ -opioid receptor antagonists reduced ethanol drinking in selectively bred alcohol-preferring rats and normal rats. Targeted gene mutation (knockout) strategies have produced mice that lack either μ - or δ -opioid receptors. μ -Opioid receptor knockout mice avoid alcohol, but δ -opioid receptor knockout mice self-administer more alcohol. The excess alcohol administration in δ -opioid receptor knockout mice is considered to be due to increased μ -opioid receptor activity, because μ - and δ -opioid receptor systems may oppose one another.

Cellular action of ethanol on hypothalamic opioid peptides Using primary cultures of hypothalamic neurons, it has been shown that low concentrations of ethanol acutely stimulate β -endorphin release from cultured hypothalamic neurons. Similarly, a single administration of ethanol acutely stimulated the plasma levels of β -endorphin in male rats. However, an inhibitory effect of chronic ethanol on β -endorphin secretion has been demonstrated in both *in vivo* and *in vitro* studies. Hypothalamic proopiomelanocortin gene expression also increases following acute ethanol, but it decreases following chronic ethanol in both *in vivo* and *in vitro* systems. These functional changes in β -endorphin neurons following ethanol treatments parallel many behavioral changes observed following ethanol use in humans. It is proposed that by enhancing opioid activity, ethanol could compensate for

Figure 1 The effects of single or moderate ethanol administration (acute ethanol) and binge or long-term ethanol administration (chronic ethanol) on the β -endorphin system. Acute ethanol enhances and chronic ethanol suppresses β -endorphin synthesis or release by altering the activity of key intracellular transducers (cAMP, Ca^{2+} , and PKC). Up arrows symbolize upregulation; down arrows symbolize downregulation; IP₃, inositol triphosphate; PI cycle, phosphatidylinositol cycle; PPI, inorganic pyrophosphate.

constitutive deficiencies of endogenous opioids that may contribute to ethanol self-administration. In increasing the sensitivity of the opioid peptide as well as other neurotransmissions, ethanol could increase the rate of ethanol self-administration. Ethanol may produce tolerance and physical dependence, in part, by altering opioid neurotransmissions.

Studies using hypothalamic cells in primary cultures have elucidated primary transduction pathways for the ethanol action on β -endorphin release. These studies suggest that acute ethanol stimulates β -endorphin secretion, possibly by activating the cAMP cascade, protein kinase C (PKC), and Ca^{2+} -dependent mechanisms (Figure 1). The ethanol action on the cAMP system appears to involve the inhibition of adenosine uptake, leading to increasing extracellular levels of adenosine and the activation of membrane adenosine receptors and, consequently, to an increase in cAMP production and β -endorphin secretion. Acute ethanol action on β -endorphin release also involves calcium entry via the activation of voltage-dependent calcium channels. Furthermore, acute ethanol stimulates the expression and translocation of δ - and ϵ -PKC isoforms to activate β -endorphin release. In contrast to this, chronic ethanol causes the development of tolerance and desensitization of β -endorphin neurons due to reduction in the production and translocation of δ - and ϵ -PKC isoforms and the production of intracellular levels of cAMP. The inhibitory effect of chronic ethanol on cAMP is a result of the development of heterologous desensitization of adenosine, prostaglandins, and adrenergic receptors on these neurons. Hence, the changes in signal transduction could be critical for the adaptation of β -endorphin neurons to chronic ethanol exposure (Figure 1).

Genetic Aspects

Findings from twin, adoption, and cross-fostering studies and pedigree analyses have indicated that genetic and environmental factors play an important role in determining an individual's vulnerability to alcoholism. Although a multitude of biological differences have been found as a function of a family history of alcoholism, a number of studies suggest that diminished endogenous hypothalamic opioid activity and opioid receptor polymorphisms may increase an individual's vulnerability to becoming an alcoholic.

Genetic studies have shown that a genetic predisposition toward alcohol drinking is accompanied by an altered plasma β -endorphin response to alcohol. These studies have shown an altered opioid regulation of the HPA axis in family-history-alcoholism-positive individuals. Polymorphisms in opioid receptor genes and other opioid-regulated neurotransmitters has shown to be partly involved in the altered opioid regulation

of the HPA axis in family-history-positive individuals. A common A118G nucleotide exchange in exon 1 of the μ -opioid receptor has been shown to cause an Asn40Asp substitution polymorphism in the extracellular N-terminal domain of the μ -opioid receptor. It is believed that opioid receptor polymorphisms decrease dopamine secretion, which contributes to the altered capacity of the HPA axis to respond to stress, and that this may promote the use of ethanol to relieve stress.

Alcohol Effects on the Developing Brain

Alcohol abuse during pregnancy has been shown to be deleterious to the normal structural development of the fetal brain. Animal studies have also shown that alcohol alters the number and the shape of neurons in the developing brain. The alcohol effects on the developing brain are believed to cause the behavioral abnormalities seen in alcohol-exposed offspring. Animal models have proven useful in determining how alcohol exposure during development affects behavior. Using rat as an animal model, research has shown that the neurotransmitter system that regulates neuroendocrine and autonomic responses to stress is especially vulnerable to ethanol during the developmental period. Behavioral and neurochemical studies indicate that defects in the ability of these rats to respond appropriately to stress appears to be due to alterations in the function of hypothalamic neurons, including β -endorphin neurons and CRH neurons. The biological basis for the abnormalities in β -endorphin neuronal functions in animals exposed to ethanol during the fetal period is unknown, but it presumably involves an alteration in β -endorphin neuron growth and differentiation.

How ethanol affects β -endorphin neuron growth, differentiation, and neuronal connection in the CNS is not well understood. Some recent studies suggested the possibility that ethanol may reduce the production of a neurotrophic factor necessary for β -endorphin neuron growth and differentiation. One of the neurotrophic agents that affects β -endorphin neuronal growth in cultures is cAMP. Using cells from the rat fetal hypothalamic tissues, it has been shown that cAMP increases β -endorphin cell numbers and neurite growth by preventing programmed cell death. Ethanol reduces the production of cellular levels of cAMP and increases the secretion of transforming growth factor β 1 and consequently upregulates the expression of proapoptotic genes and induces programmed cell death of these neurons. The loss of β -endorphin neurons during the developmental period can lead to permanent opioid deficiency in the hypothalamus and abnormality in stress axis function.

G-proteins are membrane-bound proteins that regulate cellular adenylyl cyclase activity and maintain the production of intracellular cAMP. Recently, abnormalities in G-protein expression and adenylyl cyclase activity have been observed in lymphocytes and erythrocytes derived from alcohol-dependent individuals. Similar abnormalities in the cAMP-signaling system have been documented in high-drinking lines of rats. In nonalcoholic children of alcoholics, an enhanced expression of the stimulatory $G_s\alpha$ protein was observed in erythrocyte and lymphocyte membranes. It has been postulated that adenylyl cyclase and G-protein expression may be markers for vulnerability to alcoholism.

Ethnicity

Ethnicity and Mental Health in the United Kingdom

Problems with Existing Sources of Data

Explaining Key Findings and Contradictions

Conclusions

Glossary

Census

A census is a count or survey of all households and people within a particular location. In the United Kingdom a census has been carried out every 10 years since 1841. The 1991 Census was the first one to ask individuals to define their ethnicity.

<i>Ethnicity</i>	The identification, by self or others, with a social group and or social collectivity on the basis of shared values, beliefs, customs, traditions, language, or lifestyle.
<i>Patriarchy</i>	Traditionally means rule of the father and used to describe the dominance of men over women.
<i>Race</i>	A contentious concept within British sociology, which is normally associated with a group connected by a common biological/genetic origin, typically associated with skin color.

Introduction

In this article we consider the key findings that have emerged on ethnic differences in mental health, with particular reference to the United Kingdom. This will be followed by a brief discussion of ethnic minority people's experiences of mental health services and the implications this has for healthcare provision and practice. We will conclude with a discussion of the conclusions we can draw on ethnic inequalities in mental health and the implications this has for our wider understanding of the experiences of ethnic minority people in United Kingdom and how these relate to stress and mental health. But we begin by introducing the concept of ethnicity.

Ethnicity

Approaches to ethnicity have been concerned with understanding how ethnicity relates both to social structures and how it relates to social relationships and identities, allowing us to provide a sensitive and contextual understanding of ethnicity, rather than resort to explanations based on stereotypes. So, research in the United Kingdom has demonstrated the social and economic inequalities faced by ethnic minority people and how economic inequalities and racism relate to ethnic inequalities in physical and mental health. In addition, importance is placed on the notion of ethnicity as an identity that reflects self-identification with cultural traditions, and which provide both meaning and boundaries between groups. So, although there is strong evidence to show that socioeconomic disadvantage contributes to ethnic inequalities in health, it is suggested that there remains a cultural component to ethnicity that could play a defining role.

When considering the relationship between culture, ethnicity, and mental health, however, it is vital to avoid reducing ethnic differences in mental health to stereotyped notions of fixed cultural or biological difference. Ethnicity is considered to reflect identification

with sets of shared values, beliefs, customs, and life-styles and has to be understood dynamically, as an active social process. In particular, the influence of an ethnic identity on individuals and their health depends on the wider context in which that identity is lived.

Ethnicity and Mental Health in the United Kingdom

The difference in rates of mental illness among different ethnic groups in the United Kingdom is probably one of the most controversial issues in the health inequalities field. Given the topic, which potentially allows the alignment of mental disorder with ethnic minority status, the controversial nature of the field is not surprising. And this controversy is aggravated by the complexity of conducting research on ethnic differences in mental illness and the consequent disputed nature of research findings. Much of the controversy has focused on the high rates of hospital treatment for schizophrenia and other forms of psychosis among the African-Caribbean population, where the alignment of mental disorder with ethnicity is most apparent. Interestingly, these findings are reflected in research in the United States and the Netherlands, where black populations are also shown to have high rates of psychotic illness. In the United Kingdom, evidence suggesting low rates of mental illness among the South Asian population, but high rates of suicide and attempted suicide among young South Asian women has also caused controversy. The following provides a summary of key findings from the United Kingdom.

Psychotic Illness

Psychotic illnesses, which include schizophrenia, are relatively infrequent; they are thought to affect around one person in 250 in the United Kingdom, but often result in severe disability. Typically they involve a fundamental disruption of thought processes, where the individual suffers from a combination of distressing delusions and hallucinations.

Most research on ethnic differences in psychotic illnesses has been based on treatment rates, and over the past three decades such studies in the United Kingdom have consistently shown elevated rates of schizophrenia among African-Caribbean people compared with the white population. African-Caribbean people are typically reported to be three to five times more likely than whites to be admitted to hospital with a first diagnosis of schizophrenia. These findings have been repeated in studies that have looked at first contact with all forms of treatment, rather than just hospital services, although the rates in one such study were only twice those of the white population. Some of the more recent of these studies have also looked at

those of African ethnicity and have reported similarly raised rates of psychotic illness in this group. Explorations of the demographic characteristics of black people admitted to hospital with a psychotic illness suggest that these illnesses are particularly common among young men, and some studies have suggested that the rates are very high among young African-Caribbean people who were born in the United Kingdom, reporting that rates of first contact with psychiatric services for psychotic illness among this group are 18 times the general population rate.

Given the consistency of the evidence based on treatment statistics, it is somewhat surprising that the only national community based studies of mental illness among ethnic minority groups, the Fourth National Survey of Ethnic Minorities (FNS) and the Ethnic Minority Psychiatric Illness Rates in the Community (EMPIRIC) study, produced rather different findings. Overall, they found that Caribbean people had rates of psychotic illness that were at most twice as high as those in the general population. And when differences were considered across gender, age, and migrant/nonmigrant groups it was found that the prevalence of psychotic illness among: men; young men; and nonmigrant men; was no greater than that for equivalent white people. For example, in the FNS the annual prevalence of psychotic disorder among Caribbean men was estimated as 10 per 1000, while among white British men it was estimated as eight per 1000.

Findings on rates of psychotic illness among South Asian people are even more mixed. Studies of hospital-based treatment suggest that rates of admission for psychotic illness among South Asian people are similar to those among white people. This has been confirmed by a more comprehensive prospective study of first contact for schizophrenia with *all* treatment services in one area of London, but an earlier study using the same methods in another London district suggested that rates of psychotic illness among South Asian people were raised to similar levels to those found among black Caribbean people. Indeed, there is evidence suggesting that rates of psychotic illness among each of the ethnic minority groups defined by the 1991 Census categories are similarly raised in comparison with a white group. This, of course, suggests that it is misleading to maintain an exclusive focus on those of African-Caribbean origin when examining ethnic differences in psychotic illness in the United Kingdom.

In contrast to the findings for contact with treatment services, the community based FNS and EMPIRIC prevalence studies suggested that rates of psychotic illness might not be raised for South Asian people, and may be lower for Bangladeshi people,

than those for white British people. In support of the conclusions drawn by some researchers, these community surveys also suggested a high rate of psychosis among white people who were not of British origin.

Depression

Neurotic disorders, which include depression, are much more common than psychotic disorders. A national survey in the United Kingdom suggested that in the week before interview about one person in 16 was affected by such a disorder. They are usefully separated into two categories, anxiety and depression that, although common, do involve considerably more than a sense of anxiety or sadness. Here we will focus on depression, because of the lack of data on ethnic differences in anxiety.

According to treatment statistics, rates of depression among African-Caribbean people appear to be markedly lower than those for white people, and rates of depression among South Asian people appear to be a little lower than those for white people. For South Asian people, these findings have been confirmed in community studies, including the FNS. However, the more recently conducted, and more thorough, EMPIRIC study suggested few differences between South Asian groups and white people, with higher rates of depression among the Pakistani population.

In comparison with the high rates of treatment for psychotic illness among African-Caribbean people, the low rates of treatment for depression are a puzzle. Most factors that might be implicated in the higher rates of psychotic disorders should also lead to a higher rate for other mental illnesses. In addition, in contrast to the low treatment rates, evidence from the FNS suggests that the prevalence of depression among Caribbean people in the community is, in fact, more than 50% higher than that among whites. Moreover, that study also suggested that despite this higher prevalence, rates of treatment for depression among Caribbean people were very low.

In contrast to the low rates of hospital admission for depression among those born in the Caribbean and South Asia, it has been reported that rates of admission for depression among those living in England but born in Northern Ireland and Ireland were markedly higher than for those born and living in England. The high rate of depression among white people who were not of British origin was confirmed in the community based FNS, which reported that this group had rates that were two-thirds higher than the white British group, and was confirmed for Irish men in EMPIRIC.

Suicide

In contradiction to the apparent lower overall relative rates of mental illness among South Asian people, analyses of immigrant mortality statistics show that mortality from suicide are higher for young women born in South Asia, and this is particularly the case for very young women (aged 15–24 years), where the rate is two to three times the national average. In contrast to the findings for young South Asian women, these studies also showed that men and older women (aged 35 years or more) born in South Asia had lower rates of suicide. Analysis of the most recent data on immigrant mortality has been more detailed, because it could be coupled with the 1991 Census, which included a question on ethnicity as well as country of birth. This confirmed the overall pattern just described, but showed that the high rates appear to be restricted to those born in India and East Africa, rather than Pakistan or Bangladesh.

In terms of morbidity, rather than mortality, again the picture is mixed with studies of treatment suggesting very high rates of suicidal ideation, attempted suicide, and suicide among both male and female South Asians. In contrast, the only studies to look at suicidal thought among national community populations (the FNS and EMPIRIC) found that the rates of suicidal ideation were not raised among South Asian groups and, if anything, lower among South Asian women than white women regardless of age.

Problems with Existing Sources of Data

Although mental illness is a relatively common condition, it is difficult to measure and the defining characteristics are contested. Both the definition and the measurement of mental illness depend on the presence of clusters of psychological symptoms that indicate a degree of personal distress, or that lead to behaviors that cause such distress to others. The clusters of symptoms associated with particular forms of mental illness are clearly defined by psychiatrists, although the elicitation of these symptoms for diagnostic or research purposes can be difficult, particularly in cross-cultural studies.

One of the central problems arises from the reliance of most work on data based on contact with treatment services. Contact with treatment services, even when access is universal as in the United Kingdom's National Health Service, reflects illness behavior (i.e., the way that symptoms are perceived, evaluated, and acted upon), rather than illness *per se*. This raises a number of linked problems, particularly as illness behavior is likely to be affected by a number of fac-

tors that vary by ethnicity, such as socioeconomic position, health beliefs, expectations of the sick role, and lay referral systems. And these problems become particularly important for work on rates of psychosis, where contact with services might be against the patient's wishes. So, despite the consistency of research findings showing that African-Caribbean people have higher rates of treatment for psychosis, some commentators have not accepted the validity of the interpretation of these data and continue to suggest that a higher incidence (rather than a higher treatment rate) remains unproven, because of the serious methodological flaws with the research that has been carried out.

Briefly, the kind of problems that are focused on include: underestimation of census-based denominators for African-Caribbean people, leading to overestimation of admission rates (although not to the extent that could explain the many times higher rates of admission); overestimation of first onsets of psychosis, because of under-identification of previous episodes for African-Caribbean people (because of high geographical mobility leading to records of previous admissions being missed and a reluctance to disclose previous diagnoses because of a concern about the impact of these on how they might be managed); variations in the routes of admission and treatment by ethnicity, with African-Caribbean people over-represented among patients compulsorily detained, more likely to have been in contact with the police or forensic services prior to admission (despite them being both less likely than whites to display evidence of self-harm and no more likely to be aggressive to others prior to admission), and more likely to have been referred to these services by a stranger rather than by a relative or neighbor. Taken together, these comments suggested that there are a variety of potential problems with existing work and, consequently, that there must remain some doubt about the higher rates of psychosis reported among the African-Caribbean group.

It is equally possible that the reported differences between white and South Asian groups and the inconsistencies found in these could, as for the African-Caribbean group, be a result of the methodological limitations of studies in this area. In addition to the difficulties of relying on treatment data, outlined above, the lower rates of mental illness among South Asian people could reflect language and communication difficulties, or a general reluctance among South Asian people to consult with doctors over mental health problems. More fundamentally, they may reflect a difference in the symptomatic experience of South Asian people with a mental illness compared

with white people. In particular, it has been suggested that South Asian people may experience particular culture-bound syndromes, that is a cluster of symptoms which is restricted to a particular culture, such as sinking heart, and consequently not be identified as mentally ill.

Explaining Key Findings and Contradictions

There a number of explanations considered for ethnic differences in mental health and these are similar to those considered for other ethnic inequalities in health in the epidemiological literature. These include migration, genetic differences, culture, racism, and socioeconomic position.

Migration

First, different rates of mental health across migrant and nonmigrant groups could be a consequence of factors related to the actual process of migration. Social selection into a migrant group could have favored those with a higher or lower risk of developing illness, or the stresses associated with migration might have increased risks. There is evidence to both support and counter these suggestions. In the case of the apparently higher rates of schizophrenia among African-Caribbean people in the United Kingdom, investigations of the rates of schizophrenia in Jamaica and Trinidad suggest that they are much lower than those for African-Caribbean people in the United Kingdom and, in fact, similar to those of the white population of the United Kingdom. This would suggest that the higher rates are either a consequence of factors related to the migration process, or of the greater stresses surrounding the lives of ethnic minority people in the United Kingdom.

However, there is evidence that shows that rates of schizophrenia for African-Caribbean people born in the United Kingdom are even higher than for those who migrated, suggesting that factors relating directly to the process of migration may not be involved, although these data (like most work in this area) are dependent on a very small number of identified cases.

Genetic Differences

As with all work on ethnicity and health, there has been discussion of the possibility that differences may be a consequence of a genetic factor that correlates with ethnic background, but little supporting evidence has been marshaled. Evidence suggests large differences in risk within ethnic categories, implying that any genetic basis for mental illness does not

correlate closely with ethnic background. For example, the evidence on schizophrenia cited in the previous section, which shows that there are important differences between African-Caribbean people who stayed in Jamaica or Trinidad (who do not have raised rates), those who migrated to the United Kingdom (who appear to have raised rates), and those who were born in the United Kingdom (who appear to have markedly raised rates), suggests that the higher rates cannot be straightforward consequence of ethnic differences in genetic risk.

Culture

Not surprisingly, most research that has focused on cultural explanations for ethnic differences in mental health has based the cultural argument on speculative and stereotyped characterizations of the cultures of ethnic minority groups, which do not acknowledge the dynamic nature of culture.

It has been suggested that overall lower rates of mental illness among South Asian people could be a consequence of a strong and protective Asian culture, which provides extended and strong communities with protective social support networks. In contrast, in the attempt to explain the high mortality rates of suicide among young women born in South Asia and living in the United Kingdom, South Asian communities are portrayed as constraining, demanding, and conflictual, rather than supportive and cohesive, and so contributing to the high suicide rates.

Of course, such stereotypes will not hold when closely examined. For example, despite the focus on patriarchal South Asian families, there are, in fact, great similarities between the motives of white and South Asian patients for their suicidal actions. So, although it is worthy of considering how culture informs our understanding of ethnic minority people and their experiences of illness, it is necessary to question the stereotypes we use and to understand ethnic identities as dynamic and dependent on context.

Racism and Socioeconomic Position

Different rates in mental health across different ethnic groups might be a consequence of stress resulting from the different forms of discrimination and racism that ethnic minority people face in the United Kingdom. This could be a direct result of the experience of discrimination and harassment, or a result of the social disadvantages that racism leads to. It would not be surprising if the poor run-down, inner city environments and poor housing that many ethnic minority people live in, and their poorer employment prospects and standards of living, led to greater mental distress. As elsewhere in the ethnicity and health

field, there has been considerable criticism of the failure to take into account explanatory variables related to social disadvantage in research that links ethnicity to poor mental health, as there is a strong possibility that these underlie the relationship. And there is a growing body of evidence linking racism and discrimination directly, and indirectly, to adverse mental health outcomes.

Conclusions

This article suggests that many basic questions concerning the relationship between ethnicity and mental health remain controversial. There remains a question of whether the use of western psychiatric instruments for the cross-cultural measurement of psychiatric disorder is valid and produces a genuine reflection of the differences between different ethnic groups. This has been raised particularly in relation to the low detection and treatment rates for depressive disorders among South Asians, but may apply to other disorders and other ethnic minority groups. It is also likely that treatment-based statistics do not accurately reflect the experiences of the populations from which those in treatment are drawn.

Perhaps, as other writers have pointed out, the most important conclusion to draw is that it is vital to avoid reducing ethnic differences in mental health to stereotyped notions of fixed cultural or biological difference, there is a need to explore the factors associated with ethnicity that may explain any relationship between ethnicity and mental health, such as the various forms of social disadvantage and consequent stressors that ethnic minority people face. And it remains important to explore how racism and the social disadvantages that this leads to structure the experiences of ethnic minority people when they come into contact with mental health services. Despite this, the focus on biological rather than social explanations for ethnic differences in mental illness continues in both the United States and the United Kingdom.

Utility of the Stress Response

Phylogeny of the Stress Response

How Does the Stress Response Help?

Adaptive Regulation of Stress Responsiveness

Mismatch between Ancestral and
Modern Environments

Glossary

<i>Defense</i>	A trait that is latent until aroused by threatening situations in which it is useful.
<i>Natural selection</i>	The process by which genes that provide a fitness advantage become more common from generation to generation and those that decrease fitness become less common, thus shaping adaptive traits, including defenses.
<i>Phylogeny</i>	The evolutionary history of a trait or a species.
<i>Trade-offs</i>	The fitness costs and benefits of a trait whose net effects yield a selective advantage.

Evolution is the process in which traits such as the capacity for the stress response are shaped by natural selection. Understanding the evolutionary history of a trait, how it gives a selective advantage, and the costs it imposes can help to illuminate its design and regulation and can guide research into its mechanisms and control. The stress response has been shaped by natural selection to increase the ability of organisms to cope with situations that require action or defense. Stress-related mechanisms emerged early in the history of life. Like all traits, they have costs as well as benefits. Because the stress response is so often associated with negative events, its utility has often been neglected. In particular, the release of glucocorticoids, which is often thought to be the hallmark of the stress

response, may in fact exist, in part, to protect against other aspects of defensive systems.

Utility of the Stress Response

The vast bulk of research on stress has investigated its causes, mechanisms, and effects. An evolutionary approach instead addresses two very different and relatively neglected questions: (1) How does the stress system give a selective advantage and (2) what is the evolutionary history of the stress system? The answers to these questions provide a foundation in Darwinian medicine for understanding why the stress response is the way it is and why it causes so much suffering and disease. The first and most important contribution of an evolutionary perspective on stress is a clear focus on its utility. The stress system is a complex, sophisticated, and carefully regulated adaptation that has been shaped by natural selection because it gives a selective advantage. That advantage must be substantial in order to outweigh its huge costs. The idea that stress is useful is by no means new. In fact, the very phrase Hans Selye chose to describe it, the general adaptation syndrome, emphasizes its utility. Despite this early emphasis on its benefits, as the idea of stress entered the popular imagination there was a tendency to emphasize its dangers so that the fundamental fact of the utility of the stress response was often forgotten.

Stress and Other Defenses

Other defenses are also often confused with the problems they protect against. The capacities for pain, fever, vomiting, cough, and inflammation are often thought of as medical problems, although a moment's thought reveals that they are useful protective reactions. The ubiquity of the illusion that defenses are abnormalities arises from several sources. First, defenses are often associated with some kind of suffering and therefore seem maladaptive. Unfortunately, however, discomfort is itself probably one aspect of a mechanism that makes it useful. Second, they are reliably associated with disadvantageous situations, so the association bias makes it seem as if they are the problem. Finally, it is possible to use drugs to block the expression of many defenses with very little harm, completing the illusion that defenses are useless. In fact, blocking

a defense can be harmful. For instance, suppressing cough in a patient with pneumonia makes it harder to clear the infection and may lead to death, and stopping the diarrhea of a person with a serious intestinal infection may lead to complications. Blocking fever, however, usually has little effect on the speed of recovery from a cold. When blocking a defense is not dangerous, this is because the body has backup protective mechanisms and because the regulation mechanism seems to be set to a hair trigger that expresses the defense at the slightest hint of danger.

Situations in Which Stress Is Useful

Stress, like fever and pain, is useful only in certain situations. Such traits lie latent until aroused by the particular circumstances in which they are useful. This means that the evolutionary explanation for such traits cannot be summarized in a single function. Instead, the inducible defenses give an advantage by changing multiple aspects of the body that increase its ability to cope effectively with the adaptive challenges that arise in a particular situation. One defense may have many aspects that serve many functions. So, the first step in understanding the adaptive value of stress is not to try to specify its function but to understand the exact situations in which the stress response is useful. To do that, we need to go back to the very origins of complex life forms 600 million years ago. If a very primitive organism had only two states, what are they? The answer is quite straightforward: activity and rest. This is a fundamental divide, one that is maintained even in our biochemical and nervous systems. Biochemical pathways are divided into the catabolic, in which energy is used, and the anabolic, in which energy is stored and tissues are repaired. Parallel to this division are the two arms of the autonomic nervous system. The sympathetic system, which is activated as part of the stress response, increases arousal, blood pressure, heart rate, respiratory rate, and physical activity and institutes other endocrine and physiological changes necessary for action. The other half of the autonomic nervous system, the parasympathetic, inhibits muscular activity, stores energy, and shunts blood to digestion and bodily repair. Is stress, then, the same as arousal for action? Not exactly. As soon as a generic state of arousal was well established, natural selection probably began to differentiate it into subtypes to better meet the demands of different kinds of challenges. Here again, the main bifurcation is quite clear. Arousal is useful in two different situations: threats and opportunities. This division is also represented in our nervous systems. As Gray and others have pointed out, the brain seems to have moderately distinct systems for behavioral inhibition and for reward

seeking. The corresponding behaviors are said to be defensive or appetitive and are associated with feelings of fear/pain or pleasure. In psychology, the same division is recognized in the distinct cognitive states promotion versus prevention.

Phylogeny of the Stress Response

Cross-Species Comparisons

Comparisons among different species can help to reconstruct the phylogeny of the stress response. All vertebrates have the proopiomelanocortin (POMC) molecule that gives rise not only to adrenocorticotrophic hormone (ACTH) but also to opiate-like peptides. It is intriguing to note that these molecules, with their related functions, are derived from the same parent molecule. All vertebrates also make corticosteroids. Peptide sequences very similar to those of human ACTH are found not only in mammals but also in amphibians and reptiles and even in insects, mollusks, and marine worms. Interestingly they are usually associated with immune cells, equivalent to macrophages, where they set defensive processes in motion. ACTH has long been closely associated with other signaling molecules such as corticotropin releasing hormone (CRH), biogenic amines such as epinephrine and norepinephrine, steroids such as cortisol, cytokines such as interleukin-1, and nitric oxide. All these substances are crucial to defensive systems. The remarkable thing is that genetic sequences for these molecules have not only been conserved over hundreds of millions of years but they continue to serve closely related defensive functions. Why have they changed so little? If a single molecule has several essential functions, this creates a strong selective force against mutations that change the sequence. By contrast, mutations that result in the differentiation of different classes of receptors in target tissues can slowly specialize the responses of that tissue to the signal molecule. And they have, judging from the proliferating classes and subclasses of receptors that are now being discovered.

Cost-Benefit Trade-Offs

Why is the stress system not better? It could provide more effective protection against danger – but only at a still greater cost. *Drosophila* have been bred to resist the stress of food shortage. After 60 generations of such selection, the new strain is 80% more resistant to starvation. However, the larvae are more likely to die, and development is slowed. Similar results have been found for selection of resistance to other stressors and in other species. Like everything else in the body, stress responses are shaped by trade-offs, some-

times with benefits and costs occurring in different parts of the life cycle.

The mechanisms that regulate the responsiveness of the stress system are shaped by the trade-off between the long-term costs and the immediate benefits of a relatively quick or intense or prolonged stress response. It has been hypothesized that the individuals who are most resilient or resistant to the effects of stress on physiology or behavior are the ones least vulnerable to stress-related diseases. However, are these individuals resilient to all stress-related disorders, or are there situations in which resilience to some disorders means vulnerability to others? The answer is not known, but given the large number of physiological systems affected by stress and/or glucocorticoids, it is unlikely that resilience to one stress-related disorder necessarily protects against all.

Another trade-off reflects the benefits and costs of habituation. For instance, rats exposed to some repeated stressors, particularly those that are mild and cognitive in nature, habituate to that stressor. The hypothalamic-pituitary-adrenal (HPA) response is lower to the n th exposure than to the first exposure. Such habituation seems adaptive for most situations; if the stressor is known and can be easily coped with, then the HPA response should be moderated. Such habituation would, at the very least, conserve resources. However, it would be maladaptive to habituate to stressors that do present some danger. These trade-offs have shaped the brain mechanisms that regulate habituation.

There are interesting sex differences in the habituation of the stress response, with some evidence indicating that habituation occurs in male but not in female rats. Such findings suggest that the selection forces acting on male and female rats may have differed enough to shape distinctly different patterns of habituation. Research is now addressing whether habituation occurs with some stressors in males but with others in females.

Stress responses in adult animals are profoundly affected by early environmental events such as prenatal stress and variations in maternal care. The effects of variations in maternal care are transmitted across generations, with offspring that experience high maternal care exhibiting lower stress responses and providing high maternal care themselves. Such effects seem adaptive in that offspring are likely to experience an environment similar to that of their parents. So, for example, mothers providing low maternal care have high stress responses and so do their offspring when they become adults. However, when cross-fostered to other mothers, the offspring show patterns of stress responsivity similar to that of their foster mother and not their biological mother. Such

results suggest that stress responsivity and maternal care are not simply genetically transmitted but are also regulated by early experiences. Such regulation is seen in other mammals and even plants. Some of such transmission across generations may arise from facultative mechanisms that evolved to adjust the system based on early life experiences, and some may arise from more general learning mechanisms.

Difficulties in Defining Stress

The human mind seems wired to try to make neat categories with sharp boundaries, perhaps because we communicate with words and this requires dividing the world up into categories even when that is unnatural. This leads to a tendency to try to make sharp distinctions between different states that may, in fact, overlap considerably. States of defensive arousal, for instance, are different from states of arousal for seeking food, but there is no reason to expect that the differentiation is complete. For instance, cortisol secretion is aroused by opportunities as well as threats. In fact, cortisol is even involved in reward mechanisms. Thus, any attempt to define the stress response in terms of cortisol arousal is doomed. For that matter, any attempt to define stress or the stress response is liable to be an exercise in frustration for the evolutionary reason that the system does not have sharp boundaries or a single function. The closest we can come to a defining characteristic is the kinds of situations in which stress has given a selective advantage, and those situations are not sharply defined. The stress system was, after all, not designed by an engineer but shaped by a process of tiny tinkering changes. The long unsatisfying history of attempts to define stress and the wish, expressed by many researchers, that the term would go away, arise from this difficulty. Even after defensive arousal was differentiated considerably from appetitive arousal, there were undoubtedly advantages to further differentiating subtypes of stress responses to match specific challenges. Thus, different situations – a predator, a high place, injury, infection, starvation, loss of a status battle, and speaking in public – all seem to have shaped somewhat different defensive responses. These responses are only partially differentiated from a more generic response, so they have overlapping characteristics with functions in common. Attempts to sharply distinguish different kinds of anxiety disorders are as frustrating as attempts to define stress itself and for the same reasons. New attempts to study anxiety disorders in the context of normal anxiety will be helpful.

How Does the Stress Response Help?

Immediate Response

These difficulties notwithstanding, a stress response is a coordinated pattern of changes that is useful in situations in which the organism is faced with possible damage or a loss of resources. The next question is: How is it useful? Even before Selye, Walter Cannon provided some answers. In situations that might require fight or flight, he observed the utility of increased heart rate and contractility to speed circulation, increased rate and depth of breathing to speed gas exchange, sweating to cool the body and make it slippery, increased glucose synthesis to provide energy, shunting of blood from gut and skin to muscles, increased muscle tension to increase strength and endurance, and increased blood clotting in preparation for possible tissue damage. More recently, others have demonstrated faster reaction times and cognitive benefits as a result of sympathetic arousal. These immediate responses are mostly mediated by the sympathetic nervous system and the associated release of epinephrine from the adrenal medulla.

Adrenal Cortical Response

However, the stress system also includes a more delayed-response release of cortisol from the adrenal cortex, although this system does have more rapid effects (such as fast negative feedback) that are probably mediated by putative membrane steroid receptors. This is initiated by neural signals to the hypothalamus, which releases CRH, which in turn results in the secretion of ACTH from the anterior pituitary gland on the bottom of the brain. The ACTH induces cortisol synthesis and release from the adrenal gland. The whole system is called the HPA system because the signal acts via the hypothalamus, the pituitary, and the adrenal glands. Many actions of the HPA system seem, like those of the sympathetic system, well designed for acute action. It changes physiology so the liver breaks down glycogen into glucose, and it alters cells so glucose can get in more readily. Through different populations, CRH not only releases ACTH, but it also directly increases anxiety and arousal and activates cells in the locus coeruleus, the brain center where the cell bodies for most noradrenergic neurons are located. All in all, the system seems admirably designed to get the organism ready for action. Indeed, both branches of the system are readily aroused by exercise, and trained athletes, far from having low levels of cortisol, have chronic high levels – just the thing for a person who frequently exerts him- or herself.

Association with Negative Events

So, why should the stress system as a whole be associated so closely with bad events instead of positive ones? To answer that question, we need to understand why the components of the stress system are carefully packaged. If the stress is so useful, why is stress not expressed all the time? There are at least three good reasons why it is not. First, it is expensive in terms of calories. No organism can afford to waste effort. Second, it interferes with other adaptive behaviors. A vigilant organism has less time for finding food and eating, to say nothing of mating. Finally, and most important, some changes that give an advantage in the face of threats may also cause tissue damage. For this reason, they need to be carefully sequestered, except in those few circumstances in which the costs are outweighed by the benefits. This helps to explain why some aspects of the stress response are associated more with negative than positive arousal. The benefits of a stress response that increases the likelihood of catching prey may sometimes be worth it, but if a stress response prevents being caught as prey, this is always worth it, even if substantial damage results from the stress response itself. This helps to explain why the stress response, despite its costs, is so ubiquitous. An optimal regulatory mechanism will express a stress response whenever, on average, it is worth it. Given the uncertainties of environmental cues and the potential life-saving effects of the stress response, there will be many instances where the expression of stress is worthwhile, even though there is only a small chance that danger is actually present. The global conclusion is that the damage caused by stress responses is not necessarily from abnormal stress. Some components of the stress response may be a part of the response specifically because they are too damaging to be expressed except when they protect against great danger. There is every reason to think that normal stress, like every other bodily trait, has costs as well as benefits. This idea is expressed in the concept of allostasis, as proposed by McEwen and colleagues, which emphasizes the short-term benefits and the long-term costs.

That a normal stress response might be crucial for optimal physiological functioning has implications for recent notions about pharmacological therapies for reducing perceived stress. For example, if a drug such as a CRH inhibitor blocks all stress response at the brain level, then how does the body react to what may be real requirements for increases in energy use and how do systems that are generally opposed in functions to those of glucocorticoids, counterregulatory systems such as the regulation of insulin release, stay in check? Furthermore, there are many indica-

tions in both human and animal studies of mismatches between perceived stress or behavioral indices of stress and HPA activation. The extreme of an absent stress response is, of course, Addison's disease. Thus, although the cognitive nature of many current human stressors results in costs disproportionate to actual threats, from an evolutionary point of view the general inhibition of stress responses is by no means optimal. It would be ironic as well as tragic if the history of the excessive use of cortisone were to repeat itself with a new generation of drugs that block the stress response.

Cortisol as Protection against Other Aspects of Stress

If some aspects of the stress response cause harm, has selection shaped systems to protect against this damage? In 1984, Munck and colleagues reviewed the actions of cortisol and said, "We propose that stress-induced increases in glucocorticoids levels protect, not against the source of stress itself, but rather against the body's normal reactions to stress, preventing those reactions from overshooting and themselves threatening homeostasis." They noted that many inflammatory diseases had been attributed to overproduction of cortisol until 1941, when adrenal steroids were shown to decrease inflammation. Subsequent demonstrations showed that steroids inhibit the production of cytokines, prostaglandins, and other mediators of the immune response, thus decreasing immune function. This is just the opposite of what would make sense as protection from danger, but it is entirely consistent with a role in protecting against damage from immune system activation induced by other changes. It is now clear that the effects of glucocorticoids on immune function are much more complicated than originally thought. Added to this are recent novel findings regarding the effects of glucocorticoids on the brain versus the body on the regulation of energy balance and fat deposition that suggest that our assumptions about the physiological and neural functions of glucocorticoids will continue to be significantly challenged.

Adaptive Regulation of Stress Responsiveness

The recognition that a moderately responsive stress system is optimal is quickly leading to a consideration of the adaptive significance of variations in stress responsiveness. Several lines of thinking addresses the adaptive significance of innate individual differences in stress responsiveness. The first attempts to explain the growing evidence for a bimodal pattern

of stress response in some organisms, with some individuals responding quickly and strongly and others showing a much more restrained response. It has been suggested that these distinct patterns reflect distinct patterns of adaptation; a hawk pattern that is optimal in crowded situations and a dove pattern that is optimal when population density is low. The different strategies are hypothesized to be the products of frequency-dependent selection. There is also increasing evidence that maternal effects on an offspring's stress responsiveness may be adaptive. Mothers exposed to stressful environments give birth to offspring with especially responsive stress systems that may give them an advantage in harsh environments. The same evolutionary forces may have shaped mechanisms that explain the connection between early abuse or neglect and increased stress vulnerability.

Mismatch between Ancestral and Modern Environments

Much has been made of the differences between our environment and that of our ancestors. In the case of stress, this argument comes in several flavors. Some suggest that life is more stressful now than it was for our predecessors. Special aspects of our environment do cause new kinds of stress. Working in a bureaucracy is tedious and political at best. Driving to work, living in a ghetto, running a corporation, working in a factory – these all arouse the stress system. Despite the amount of stress we experience, however, our ancestors almost certainly experienced more. With no police, no food reserves, no medicine, no laws, rampant infections, and prevalent predators, danger could come at any time. True, social groups were closer, kin networks were stronger, and people spent all their time with one another and none alone reading books. Still, life was hard. Perhaps in that environment, where stressors were more often physical, the stress response was more useful than it is now. Today, we mainly face social and mental threats, so the actions of the HPA system may yield net costs. This is plausible and supports the many efforts to reduce stress and to find drugs that block the stress response. This brings us back to the very concept of stress as a mismatch between the demands made on an individual and that individual's ability to meet those demands. We think of these demands as coming from the outside, and sometimes they do, as when we are attacked by the proverbial tiger. But most stresses in modern life arise not from physical dangers or deficiencies but from our tendency to commit ourselves to personal goals that are too many and too high and to ruminate about them. When our efforts

to accomplish these goals are thwarted or when we cannot pursue all the goals at once and must give something up, the stress reaction is expressed. In short, much stress arises, ultimately, not from a mismatch between our abilities and the environment's demands, but from a mismatch between what we desire and what we can have.

Glossary

<i>Excitatory postsynaptic potential (EPSP)</i>	The electrophysiological response evoked by glutamate released from mammalian nerve terminals.
<i>Excitotoxicity</i>	Cellular injury caused by compounds, such as glutamate, that are both neuroexcitatory and neurotoxic.
<i>Ionotropic receptor</i>	An ion channel with binding affinity for a particular ligand, in which ligand binding promotes channel opening.
<i>Long-term depression</i>	A long-lasting, stable reduction in the size of the postsynaptic response.
<i>Long-term potentiation</i>	A long-lasting, stable increase in the size of the postsynaptic response.
<i>Metabotropic receptor</i>	A macromolecule with binding affinity for a particular ligand, in which ligand binding produces a physiological effect through coupling to a GTP-binding (G) protein.
<i>Receptor desensitization</i>	An agonist-induced reduction of the response transduced by a receptor.

Transporter

A membrane-bound macromolecule that selectively binds a particular ligand, transfers it across the cell membrane (both with and against its concentration gradient), and releases it on the other side.

Several naturally occurring amino acids possess neuroexcitatory properties and may be transmitters. A large amount of aspartate ($\sim 3 \mu\text{mol g}^{-1}$ wet weight) is present in the brain, as are small amounts of other excitants, including cysteine sulfinic acid and quino-
linic acid. However, current evidence favors glutamate as the transmitter used by nearly all excitatory pathways in the mammalian central nervous system. These pathways include many that are known to be involved in responses to stress, such as the outflow from the hippocampus to the hypothalamus. Therefore, only glutamate mechanisms are covered here.

Synthesis and Release

The cerebral cortex and other higher brain centers contain more glutamate than any other part of the body, approximately $12 \mu\text{mol g}^{-1}$ wet weight. This is more than twice the glutamate content of the spinal cord and much higher than the glutamate content of the peripheral organs. Immunocytochemical labeling methods show an excess of glutamate in excitatory neurons and their axon terminals. The terminals contain small, clear, round synaptic vesicles. The postsynaptic element is usually a dendritic spine with a broad postsynaptic density. The postsynaptic density contains glutamate receptors and their associated signaling molecules. Approximately 60–70% of all synapses in the brain appear to be glutamate synapses (Figure 1).

(6) Voltage-dependent Ca²⁺ channel. (7) Exocytotic release. (8) Type III metabotropic receptor. (9) AMPA receptor. (10) NMDA receptor. (11) Type I metabotropic receptor. (12) G_q. (13) Plasma membrane transport. (14) Glutamine synthetase. (15) Diffusion and terminal uptake of glutamate.

Glutamate can be synthesized by at least six different metabolic routes. However, most of the glutamate that is used as a transmitter is synthesized from glutamine. This biosynthetic process involves cooperation between nerve terminals and the adjacent astrocytes. Glutamate is taken up by astrocytes and converted to glutamine by glutamine synthetase, an enzyme expressed by glia but not by neurons. The glutamine synthetase reaction requires ATP. Astrocytic end feet, enriched in glucose transporters, cover virtually all capillary walls in the brain. Glutamate transport into the astrocytes stimulates glucose uptake by these cells. Glutamine produced by the astrocytes diffuses into the extracellular space and is taken up by the nerve terminals. Glutamate nerve terminals are enriched in phosphate-stimulated glutaminase, a mitochondrial enzyme that hydrolyzes glutamine to glutamate. This synthetic pathway is referred to as the glutamate–glutamine cycle. The glutamate–glutamine cycle provides a mechanism for coupling glutamate transmission with glucose use. The energy demands of this cycle account for approximately 85% of total brain glucose use!

The expression of vesicular glutamate transport determines that a particular synaptic terminal will release glutamate. The vesicular transporters are very specific for glutamate and exclude even closely related amino acids, such as aspartate. Transport is driven by an inside-positive vesicular membrane potential and a pH gradient, which are both created by vacuolar H⁺-ATPase activity. Three cDNAs that encode distinct vesicular glutamate transporters have been cloned. The transporters are expressed by different neuronal

populations. Two of the vesicular transporters were originally identified as inorganic phosphate transporters located on the plasma membrane of the nerve terminal. It is now known that the transporter is incorporated into the vesicular membrane in an orientation that allows for the inward transport of glutamate. After exocytosis, the transporter is transiently incorporated into the plasma membrane in the opposite conformation (inside-out relative to the synaptic vesicle). In that conformation, it can transport inorganic phosphate into the terminal.

Glutamate is released on nerve terminal depolarization by Ca²⁺-dependent exocytosis. In the mature brain, the opening of P/Q-type Ca²⁺ channels in the nerve terminal membrane provides the bulk of the Ca²⁺ required to drive this process. Glutamate can regulate its further release by feeding back onto terminal autoreceptors. Glutamate release is also regulated by the previous activity of the synaptic terminal, by other transmitters that may be present locally in the extracellular fluid, and by products of cell metabolism, such as adenosine and arachidonic acid.

Glutamate Receptors

Glutamate acts on several structurally and pharmacologically different types of membrane receptors, both ionotropic and metabotropic. The ionotropic glutamate receptors, for historical reasons, are named for structural analogs of glutamate that selectively activate that particular receptor: (RS)- α -amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA) and *N*-methyl-D-aspartate (NMDA). The expression pattern, density, subunit composition, and posttranslational modification of glutamate receptors are modulated by ontogenic development and by changes in physiological and pathological state.

AMPA Receptor

Nearly all glutamate-activated fast EPSPs depend on the activation of AMPA receptors. AMPA receptors have the multisubunit structure characteristic of all ligand-gated ion channels. For AMPA receptors in particular and ionotropic glutamate receptors in general, the receptor is composed of (probably) four glycopolypeptide chains arranged like the staves of a barrel with a channel in the middle through which ions can flow. The binding of glutamate to the receptor initiates a conformational change that opens the channel and allows ion flow. AMPA receptors typically bind glutamate with low affinity ($K_D \sim 100 \mu\text{M}$) and desensitize rapidly. That is, the channel current declines to a lower steady-state level while glutamate is still bound.

The AMPA receptor forms what is known as a small cation channel. The channel is permeable to both Na^+ and K^+ . When glutamate opens the channel, Na^+ flows down its electrochemical gradient into the postsynaptic cell and K^+ flows down its electrochemical gradient out of the cell. Because the Na^+ flux exceeds the K^+ flux ($E_{\text{Na,K}} \sim 0 \text{ mV}$), the net effect is a depolarization – the fast EPSP.

Four cDNAs that encode AMPA receptor subunits, designated GluR1–4 (or GluRA–D), have been cloned. AMPA receptor subunits can form a channel either by themselves (homomeric) or with other subtypes (heteromeric). Each combination of subunits forms a channel with slightly different properties. Moreover, each of the AMPA receptor subunits can exist in flip and flop versions, depending on alternative splicing. The involvement of flip versus flop versions of the subunit in channel formation affects the extent of receptor desensitization. Molecular biological studies of the ionotropic glutamate receptors led to two surprising and unique findings. First, the ionic selectivity of the channel is determined by a single amino acid in the putative second transmembrane (actually an intramembrane) domain. This amino acid can be glutamine, asparagine, or arginine. If a glutamine is present (as in GluR1, -3, or -4), a homomeric channel has a fairly high permeability to both Ca^{2+} and Mg^{2+} . If an arginine is present (as in GluR2), any channel that includes the subunit exhibits low permeability to Ca^{2+} and Mg^{2+} . (If an asparagine is present, as in NMDA receptor subunits, the channel exhibits high Ca^{2+} permeability and low Mg^{2+} permeability). Because the great majority of AMPA receptors expressed by excitatory neurons have low Ca^{2+} permeability, they must include at least one GluR2 subunit. In contrast, many AMPA receptors expressed by inhibitory neurons lack a GluR2 subunit and thus exhibit high Ca^{2+} permeability. Second, the presence of arginine at the critical site depends on RNA editing. All AMPA receptor genes code for a glutamine residue there. Selected mRNAs are altered after transcription to code for arginine (an adenine residue is converted to inosine).

NMDA Receptor

The NMDA receptor usually coexists with the AMPA receptor in the postsynaptic membrane. However, some synapses have only AMPA receptors. Immature (or silent) synapses have only NMDA receptors. (Silent synapses show no postsynaptic response at typical resting membrane potentials, -60 to -80 mV). Like the AMPA receptor, the NMDA receptor probably consists of four glycopolypeptide subunits. cDNAs for five subunits, designated NMDAR-1 and NMDAR-2A–D, have been cloned. Native NMDA receptors appear

to consist of the NMDAR-1 subunit and at least one of the NMDAR-2 subunits. Each combination of subunits forms a channel with slightly different properties. The development of the brain involves a change in the subunit composition of NMDA receptors. During the early development of the hippocampus, for example, NMDA receptors consist predominantly of the NR1–NR2B combination. Maturation involves replacement of NR2B subunits with NR2A. The physiological effect of this substitution is a reduction in the amplitude and duration of NMDA receptor-mediated postsynaptic currents.

The extent to which NMDA receptor activation contributes to the EPSP depends on the resting membrane potential of the postsynaptic cell; its contribution increases as the membrane potential becomes less negative. At most synapses, the NMDA receptor plays an insignificant role in the EPSP evoked by a single impulse. In general, the NMDA receptor serves as a mechanism by which experience alters the synaptic transmission and properties of the postsynaptic cell for a period of hours to years. Such diverse examples of neuronal plasticity as certain forms of memory and learning, opiate tolerance, kindling-induced epileptogenesis, and differentiation of the visual system have in common the requirement of NMDA receptor activation. The NMDA receptor has several unique properties that allow it to serve this function.

First, at normal membrane resting potential, the channel is blocked by Mg^{2+} ions present in the extracellular fluid of brain. The binding of Mg^{2+} is voltage-dependent; it binds much less strongly when the membrane is depolarized. Thus, NMDA receptors are activated only when glutamate release is paired with postsynaptic depolarization. In response to a single impulse, glutamate is released from the synaptic terminal and produces a depolarization by activating AMPA receptors. However, this EPSP is too short-lived to relieve much of the Mg^{2+} block. (The EPSP is short-lived because the AMPA receptor desensitizes rapidly when activated by glutamate; the AMPA receptor has a low affinity for glutamate, causing bound glutamate to dissociate from the receptor rapidly; and the following inhibitory postsynaptic potential, IPSP, returns the membrane potential toward its resting value.) Thus, the NMDA receptor at most synapses contributes little to the EPSP. During repetitive activity ($5 \text{ impulses s}^{-1}$ or more), the postsynaptic depolarization is more prolonged and Mg^{2+} block is effectively relieved. In addition, repetitive activity reduces γ -aminobutyric acid (GABA) inhibition. Under these conditions, the NMDA receptor contributes substantially to the EPSP. Compared to the AMPA receptor-mediated component, the NMDA component is of longer duration and exhibits slow

kinetics. High-frequency activity is associated with experiences that result in memory and learning; high-frequency activity can also be pathological, as in seizures.

Second, the NMDA receptor forms a small cation channel that is permeable not only to Na^+ and K^+ but also to Ca^{2+} . Like the AMPA receptor, it is the large flux of Na^+ and K^+ through the open channel that accounts for the NMDA receptor-mediated component of the EPSP. In contrast, the smaller Ca^{2+} influx is responsible for altering the properties of the synapse and the postsynaptic cell. Because the intracellular Ca^{2+} concentration at rest is very low, even a small influx of Ca^{2+} can increase the local intracellular concentration substantially. At this higher concentration, Ca^{2+} transiently activates a number of key enzymes, including protein kinases and enzymes that synthesize the diffusible modulators, nitric oxide and arachidonic acid. The concerted activation of these enzymes leads, by a mechanism that is only partially understood, to a long-lasting (days to weeks) enhancement of the EPSP. This process is known as long-term potentiation (LTP). There is growing evidence that the initial phase of NMDA receptor-dependent LTP involves the phosphorylation of AMPA receptors by Ca^{2+} /calmodulin-dependent protein (CaM) kinase II followed by the insertion of these receptors into the postsynaptic membrane. The subunit composition of postsynaptic AMPA receptors changes. In the basal state, these receptors are composed mainly of GluR2 and GluR3 subunits. The activation of CaM kinase II results in the phosphorylation of cytoplasmic GluR1 subunits, causing GluR1–GluR2 receptors to be inserted into the postsynaptic membrane. The Ca^{2+} that enters through the NMDA channel also activates transcription factors that alter gene expression. Proteins synthesized as a result of this Ca^{2+} influx stabilize the potentiated state of the synapse. A larger or longer-lasting influx of Ca^{2+} can also enhance NMDA receptor function and initiate changes in gene expression that are potentially damaging (e.g., that lead to epileptogenesis or apoptosis). Conversely, a smaller Ca^{2+} flux through the NMDA channel (such as from stimulation at 1 Hz for 10 min in immature rats) triggers a reverse process known as long-term depression (LTD). The mechanism of LTD involves the Ca^{2+} -dependent activation of phosphatases. Both LTP and LTD are thought to be important for information storage in the brain. During the development of the nervous system, LTP appears to be part of the mechanism for strengthening synaptic connections, whereas LTD leads to disconnection of the synapse. It should be noted that the strength of glutamate transmission can also be modulated at some sites by

processes that do not include the activation of NMDA receptors.

A third unique characteristic of the NMDA receptor is that glutamate and glycine (or the closely related amino acid D-serine) serve as co-agonists. That is, both amino acids must bind before the channel can open. Glycine is present in the extracellular fluid of brain at a concentration of 1–3 μM , enough to saturate its binding site on the NMDA receptor, and there is no evidence for a specific glycine-release process at glutamate synapses. The glycine binding site on the NMDA receptor is unrelated to the glycine receptor that mediates transmission at some inhibitory synapses. The NMDA receptor also has modulatory sites for Zn^{2+} (which inhibits noncompetitively), polyamines (which act as open channel blockers at normal resting potential and as potentiators at depolarized membrane potentials), oxidation-reduction (oxidation reduces and reduction enhances channel activity), H^+ (mild acidification reduces channel activation), and dissociative anesthetics/psychotomimetic drugs such as ketamine and phencyclidine (which act as open channel blockers).

Kainate Receptor

The kainate receptor resembles the AMPA receptor with respect to structure, regulation, and ionic selectivity. Kainate activates both AMPA and kainate receptors; there is considerable overlap in agonist action on the two receptors. In general, kainate receptors are most abundant in pathways in which NMDA receptors are least abundant. Postsynaptic kainate receptors appear to play their greatest role in synaptic transmission onto glutamate neurons mainly during repetitive activity. Kainate receptors are also present on GABA neurons, where their activation can both stimulate and depress inhibitory transmission. The mechanism by which these contrasting effects occur is not entirely clear. Finally, kainate receptors are present on some glutamate preterminal axons and on portions of the synaptic terminal outside the synapse. Both low- and high-affinity receptors may be present. The activation of low-affinity kainate receptors depolarizes the terminal, reducing subsequent glutamate release by limiting the Ca^{2+} influx triggered by action potentials. Where high-affinity kainate receptors are present, their activation enhances subsequent glutamate release. These receptors also work through presynaptic depolarization. The lesser depolarization produced by the activation of high-affinity kainate receptors prolongs the action potential-induced depolarization and enhances Ca^{2+} entry into the terminal. Whether Ca^{2+} entry is enhanced or reduced by kainate receptor activation thus depends on the magnitude and duration of presynaptic

depolarization. Through the regulation of Ca^{2+} influx, kainate receptors play a crucial role in presynaptic forms of synaptic facilitation at some synapses.

cDNAs that encode three low-affinity kainate receptor subunits (GluR5–7) and two high-affinity subunits (KA1–2) have been cloned. The native receptors are composed of either a combination of low- and high-affinity subunits or exclusively of low-affinity subunits. The GluR5 and GluR6 subunits are usually subjected to RNA editing, like GluR2 AMPA receptor subunits, which has the effect of reducing Ca^{2+} permeation through any channel in which they are included.

Metabotropic Glutamate Receptors

The metabotropic glutamate receptors have been subdivided into three groups, based on their agonist affinities and their preferred signal transduction pathways. Type I metabotropic glutamate receptors (mGluR1 and mGluR5) signal mainly through the activation of phospholipase C. Type I receptors are located postsynaptically but outside the synaptic cleft. They are activated mainly during high-frequency activity when glutamate overflows the synapse. The activation of these receptors typically produces a slow depolarization due to K^+ -channel inactivation. This action may convert single action-potential firing into multiple firing. The strong co-activation of AMPA and type I metabotropic receptors (but not of either one alone) can raise intracellular Ca^{2+} enough to activate phospholipase A_2 (leading to arachidonic acid production) and, in some cases, to provoke LTP. A selective agonist for these receptors is 3,5-DHPG.

The activation of type II metabotropic glutamate receptors (mGluR2 and mGluR3) can reduce adenylate cyclase activity, open a K^+ channel and/or inhibit the opening of voltage-dependent Ca^{2+} channels. Type II receptors are typically located on the preterminal portion of the axon and on the synaptic terminal membrane outside the synapse. They are activated when glutamate overflows the synapse. The activation of these receptors reduces subsequent glutamate release. DCG-IV is a selective agonist for these receptors.

Type III metabotropic glutamate receptors are particularly sensitive to the glutamate analog L-AP4. A type III receptor serves as the postsynaptic receptor for glutamate at the synapse in the retina between the photoreceptor cell and the bipolar cell (mGluR6). At this site, the receptor is coupled to the activation of cyclic nucleotide phosphodiesterase and reduced opening of cGMP-dependent cation channels. Light reduces the spontaneous release of glutamate from the photoreceptor, leading to the enhanced opening of the cGMP-dependent cation channels with consequent

bipolar cell depolarization. The signal transduction mechanisms of the other type III metabotropic glutamate receptors (mGluR4, mGluR7, and mGluR8) are the same as those of type II receptors. Type III metabotropic receptors are present on some glutamate terminals, where they are located near the active zones. Receptor activation reduces subsequent glutamate release, probably by inhibiting the opening of voltage-dependent Ca^{2+} channels.

Termination of Action

High-affinity ($K_T = 1\text{--}10\ \mu\text{M}$) transport mechanisms remove glutamate from the extracellular space. They are dependent on Na^+ , K^+ , and energy. The transporters are glycopolypeptides expressed on the plasma membrane of glia, neuronal cell bodies and dendrites, glutamate nerve terminals, and even some cells outside the central nervous system. Plasma membrane glutamate transporters serve several functions. First, they recover transmitter for reuse (nerve terminals) or as a precursor for glutamine (astrocytes). Second, they bind glutamate after its synaptic release, thus clearing the synaptic cleft in preparation for the next impulse and limiting the diffusion of glutamate away from the cleft. The latter effect inhibits glutamate from acting on the extrasynaptic receptors or receptors located at nearby synapses. Because NMDA receptors have a high affinity for glutamate, they would be inappropriately activated if much glutamate were to escape the synaptic cleft routinely. Third, they maintain the extracellular glutamate concentration below the level that will chronically activate the postsynaptic receptors. The maintenance of a low extracellular glutamate concentration is necessary to avoid excitotoxicity, and this is largely the function of glial transporters. Indeed, glutamate transporter 1 (GLT-1; excitatory amino acid transporter 2, EAAT2), the more heavily expressed glial transporter, accounts for 1% of total cell protein! Cloning studies have isolated cDNAs for six transporters, two glial and four neuronal. GLT-1, although expressed predominantly by astrocytes, is also expressed by most glutamate neurons and has been localized to the plasma membrane of the synaptic terminal. Synaptic terminal expression of GLT-1 presumably accounts for the robust glutamate transport observed in synaptosome preparations.

Excitotoxicity

Glutamate and other excitatory amino acids can kill neurons when they are present in high concentration for a prolonged period. This occurs mainly through

the excessive influx of Ca^{2+} . When present in the cytoplasm for an extended period of time, high Ca^{2+} concentrations can activate hydrolytic enzymes that result in cellular autolysis. More important, Ca^{2+} activates phospholipase A_2 , producing arachidonic acid; converts xanthine dehydrogenase to xanthine oxidase; and activates nitric oxide synthase, producing NO. The end result of these enzymatic cascades is the production of cytotoxic oxygen and hydroxyl free radicals. Ca^{2+} can also induce programmed cell death by activating transcription factors. Ca^{2+} enters the cell through the NMDA channel, through Ca^{2+} -permeable AMPA channels, through voltage-dependent Ca^{2+} channels, and through exchange mechanisms. Excitotoxicity is probably responsible for most of the neuronal degeneration associated with stroke, epilepsy, and head trauma. Glutamate has been implicated in the pathology of amyotrophic lateral sclerosis (through the loss of plasma membrane transporter function). The pathology of Alzheimer's disease, Huntington's disease, and other neuropathological states probably also involves excitotoxicity.

Glossary

Excitotoxicity Cell injury or death caused by the excessive activation of excitatory transmitter receptors, particularly glutamate receptors. Neurons become vulnerable to excitotoxicity under conditions of reduced energy (glucose) availability and increased oxidative stress.

Hippocampus A structure in the temporal lobe of the brain that plays a major role in learning and memory processes and that is a focus of nerve cell degeneration in several prominent disorders including stroke, epilepsy, and Alzheimer's disease.

Neurodegenerative disorders Disorders characterized by progressive nerve cell degeneration in the brain or spinal cord; examples include Alzheimer's disease, Parkinson's disease, and amyotrophic lateral sclerosis.

Neuronal calcium homeostasis The ability of the nerve cell to regulate intracellular free calcium levels during physiological conditions and in response to stress. Membrane-associated ion channels, calcium transporters, and cytosolic calcium-binding proteins participate in this process.

Introduction

The major excitatory neurotransmitter in the nervous system is glutamate. Most, if not all, neurons in the brain and spinal cord express one or more types of glutamate receptors. Glutamate receptors are classified as ionotropic (ion channels) and metabotropic (linked to GTP-binding protein signaling pathways). Ionotropic glutamate receptors include N-methyl-D-aspartate (NMDA) receptors, which flux high levels of Ca^{2+} , and kainate and α -amino-3-hydroxy-5-methylisoxazole-4-propionate (AMPA) receptors, which flux mainly Na^+ . Glutamatergic synapses play major roles in most functions of the nervous system, including learning and memory and motor and sensory processing. However, the overactivation of glutamate receptors, particularly under conditions of reduced energy availability and increased oxidative stress, can damage and kill neurons. The excitotoxic mechanism, which is reviewed here, involves the massive influx of Ca^{2+} through NMDA receptors and voltage-dependent Ca^{2+} channels and the subsequent generation of reactive oxygen species (ROS) and mitochondrial dysfunction. Classic examples of excitotoxic neuronal degeneration in humans include severe epileptic seizures and stroke. There is also considerable evidence that excitotoxicity contributes to the neurodegenerative process in chronic neurodegenerative conditions, including Alzheimer's disease, Parkinson's disease, Huntington's disease, and amyotrophic lateral sclerosis (ALS). This article considers the emerging evidence that the neuroendocrine stress response, and cellular stress responses in the nervous system, might modify excitotoxic neurodegenerative processes in neurodegenerative disorders.

Figure 1 Excitotoxic mechanisms. The binding of glutamate to AMPA receptors and kainate receptors (KAR) opens the receptor channels, resulting in Na⁺ influx and consequent membrane depolarization and opening of voltage-dependent Ca²⁺ channels (VDCC). Some forms of AMPA receptor are also permeable to Ca²⁺. The binding of glutamate to NMDA receptors (NMDAR) under depolarizing conditions opens the NMDA receptor channel, resulting in large amounts of Ca²⁺ influx. The activation of metabotropic glutamate receptors (MetR) induces IP₃ production and the activation of IP₃ receptor and ryanodine receptor channels in the endoplasmic reticulum (ER) membrane, resulting in the release of Ca²⁺ from the ER into the cytoplasm. The increases in cytoplasmic Ca²⁺ levels in response to glutamate receptor activation can induce Ca²⁺ uptake into the mitochondria which, if excessive, can induce the production of reactive oxygen species (ROS) and inhibit ATP production. By activating proteases and inducing oxidative stress, Ca²⁺ is a key mediator of excitotoxic cell death. Modified from Mattson, M. P. (2003), Excitotoxic and excitoprotective mechanisms: abundant targets for the prevention and treatment of neurodegenerative disorders, *Neuromolecular Medicine* 3, 65–94.

Excitotoxic Mechanisms

Excitotoxicity is a complex process triggered by glutamate receptor activation that results in the degeneration of dendrites and in cell death. All subcellular compartments are affected by the excitotoxic process, with changes in the cytosol, mitochondria, endoplasmic reticulum (ER), and nucleus being pivotal. Normal amounts of glutamate receptor activation can damage neurons under conditions of metabolic and oxidative stress, which occur after a stroke or traumatic brain injury or in age-related neurodegenerative disorders.

Excitotoxicity is triggered by the overactivation of glutamate receptors, resulting in Na⁺ and Ca²⁺ influx across through the plasma membrane as the result of opening of glutamate receptor (AMPA–kainate and NMDA) channels and voltage-dependent Ca²⁺ channels (Figure 1). In addition, the activation of GTP-binding-protein-coupled metabotropic glutamate receptors stimulates inositol trisphosphate (IP₃) production and the release of Ca²⁺ from the ER. Depending on the particular type of neuron, its developmental stage, and various environmental factors, the relative contributions of AMPA–kainate, NMDA,

and metabotropic receptors and voltage-dependent Ca²⁺ channels to excitotoxicity may differ. An antagonist that selectively blocks one of the different glutamate receptors or Ca²⁺ channels may therefore exhibit differential effectiveness in protecting different populations of neurons against excitotoxicity. A neuron's abilities to remove and buffer Ca²⁺ are also important determinants of its susceptibility to excitotoxicity. Examples of such excitoprotective mechanisms are Ca²⁺-ATPases in the plasma membrane and ER, Na⁺/Ca²⁺ exchangers, the mitochondrial Ca²⁺ uniporter, and various Ca²⁺-binding proteins.

Both the magnitude and the duration of the increase of the intracellular Ca²⁺ concentration after glutamate receptor activation are important determinants of whether the neuron degenerates. Under resting conditions, the cytoplasmic Ca²⁺ concentration in neurons is typically approximately 100 nM. Large elevations of intracellular Ca²⁺ (low micromolar concentrations) can be tolerated as long as they are transient (recovering within seconds to minutes). On the other hand, even a lesser increase of the cytoplasmic Ca²⁺ concentration (to 500 nM, for example) that is sustained for more than 20–30 min can kill the neuron. Ca²⁺ damages dendrites and kills neurons,

Figure 2 Cresyl violet-stained coronal sections of hippocampus showing that bacterial alkaloids that activate neurotrophic factor signaling pathways protect hippocampal neurons against excitotoxic death. a, Section from a sham-operated rat not receiving the excitotoxin kainic acid; b, section from a rat administered saline for 7 days and then injected with kainic acid; c, section from a rat administered K252a for 7 days and then injected with kainic acid; d, section from a rat administered K252b for 7 days and then injected with kainic acid. (1996), Bacterial alkaloids mitigate seizure-induced hippocampal damage and spatial memory deficits. *Experimental Neurology* **141**, 287–296.

in part, by activating cysteine proteases called calpains that degrade a variety of substrates, including cytoskeletal proteins, membrane receptors, and metabolic enzymes.

Oxidative stress involves the production of ROS such as superoxide anion radical, hydrogen peroxide, and hydroxyl radical. ROS-mediated damage to proteins, membranes, and DNA plays a key role in excitotoxic damage to neurons. Glutamate-induced Ca^{2+} influx can cause ROS production by activating cyclooxygenases and lipoxygenases, perturbing mitochondrial metabolism and inducing membrane lipid peroxidation. Membrane lipid peroxidation may render neurons susceptible to excitotoxicity by impairing the function of membrane ion-motive ATPases and of glucose and glutamate transporters. The importance of oxidative stress in excitotoxicity has been demonstrated in cell culture and animal models in which antioxidants such as vitamin E, lipoic acid, and glutathione protect neurons.

Because of the high amounts of energy (ATP) required to maintain and restore ion gradients, neurons are particularly vulnerable to excitotoxicity when under conditions of reduced energy availability such as hypoglycemia and ischemia. Glutamate receptor antagonists can prevent the death of neurons under

such conditions, as can agents such as creatine that promote the maintenance of ATP levels. Damage to the DNA of neurons, such as occurs under conditions of oxidative stress or exposure to certain toxins, can render neurons vulnerable to excitotoxicity. DNA damage activates the enzyme poly-(ADP-ribose) polymerase (PARP), a nicotinic adenine dinucleotide-dependent enzyme that can consume large amounts of ATP. DNA damage can also induce the production and activation of a protein called p53, which can trigger apoptosis.

Excitotoxic neuronal death can occur rapidly as the result of massive influx of Na^+ through AMPA-kainate receptors and voltage-dependent Na^+ channels, resulting in cell swelling and lysis, a process called necrosis. Another, subtler form of neuronal death called apoptosis is characterized by cell body shrinkage, the formation of cell surface membrane blebs, and nuclear chromatin condensation and fragmentation. Excitotoxic apoptosis involves pivotal mitochondrial changes including increased membrane permeability and the release of cytochrome c. Cytochrome c then binds to a protein called Apaf-1, which mediates the activation of caspases 9 and 3. Drugs that stabilize mitochondrial membrane, as well as caspase

inhibitors, can protect neurons against excitotoxic death.

Many different signaling mechanisms can protect neurons against excitotoxicity. These include those activated by neurotrophic factors such as brain-derived neurotrophic factor (BDNF), basic fibroblast growth factor, and insulin-like growth factors. Two transcription factors that are known to induce the expression of excitoprotective genes are nuclear factor (NF)- κ B and cAMP response element binding protein (CREB). Examples of such protective genes are those encoding the antioxidant enzyme manganese superoxide dismutase and the anti-apoptotic protein Bcl-2. These endogenous protective pathways can be activated by certain drugs. For example, bacterial alkaloids that activate neurotrophic factor signaling pathways can protect hippocampal neurons against seizure-induced excitotoxic damage (Figure 2).

Evidence That Physiological and Psychological Stress Can Endanger Neurons

Early studies of the impact of stress on the brain focused on the action of sustained elevations of glucocorticoids. It was shown that damage to hippocampal neurons induced by the excitotoxin kainic acid was reduced in adrenalectomized rats and exacerbated in rats administered corticosterone. The suppression of endogenous glucocorticoid production, effected by administration of the 11- β -hydroxylase inhibitor metyrapone, significantly reduced kainic acid-induced damage to hippocampal neurons. Metyrapone administration also significantly reduced brain damage in two different rat models of stroke, a middle cerebral artery occlusion model of focal cerebral ischemia and a transient global forebrain ischemia paradigm that results in the selective loss of CA1 hippocampal neurons. The latter studies showed that both seizures and ischemia resulted in a massive stress response (i.e., large increases in plasma corticosterone levels) that was effectively suppressed by metyrapone. Consistent with a role for the elevation of glucocorticoids in the endangerment of neurons in human neurodegenerative conditions are data showing that plasma glucocorticoid levels are increased in patients with temporal lobe epilepsy; stroke; and Alzheimer's, Parkinson's, and Huntington's diseases. Not only were levels of circulating glucocorticoids shown to be elevated in stroke patients and in patients experiencing severe epileptic seizures, but increased levels and duration of elevation were correlated with worse outcome. Despite these and other compelling data, clinical trials of agents that

suppress glucocorticoid production in these disorders have not yet been pursued.

Recent animal studies have shown that physiological stress (physical stressors such as cold temperature or pain and psychological stressors such as crowding or exposure to dominant males) can endanger neurons in the brain. The subjection of adult rats to chronic stress resulted in the atrophy of apical dendrites of hippocampal CA3 pyramidal neurons. The subjection of adult rats to an intermittent stress regimen resulted in an increase in vulnerability of their hippocampal neurons to seizure-induced injury.

Stress Hormones and Excitotoxicity

Studies of primary hippocampal and cortical neurons in cell culture have provided direct evidence that glucocorticoids can increase neuronal vulnerability to excitotoxicity. Based on analyses of the effects of glucocorticoids on glucose uptake and metabolic parameters (e.g., ATP levels) in cultured neurons, Sapolsky and coworkers proposed that a primary mechanism underlying the endangering effects of glucocorticoids involves impaired energy availability. This hypothesis is consistent with many studies showing that neuronal vulnerability to excitotoxicity is increased under conditions of reduced energy availability. Further supporting the metabolic compromise hypothesis are data showing reduced energy availability to neurons in Alzheimer's disease. The exposure of cultured hippocampal neurons to corticosterone resulted in a reduction in the level of glucose transport. It has not been established whether the adverse effect of glucocorticoids on glucose transport is a transcription-dependent process mediated by classic steroid receptors. Indeed, an alternative mechanism of action is suggested by data showing that the inhibition of glucose transport occurs rapidly and requires higher concentrations of corticosterone than would be expected for a receptor-mediated process.

Measurements of intracellular calcium levels in hippocampal neurons exposed to glutamate and other excitatory amino acids have shown that glucocorticoids disrupt cellular calcium homeostasis and promote calcium overload. It is not known whether this calcium-destabilizing action of glucocorticoids can be explained solely on the basis of impaired glucose uptake and ATP depletion or whether it involves one or more of the recently described actions of glucocorticoids on ion channel function. Interestingly, estrogen protects cultured hippocampal neurons against excitotoxic, metabolic, and oxidative insults by a mechanism involving the suppression of oxidative stress. In particular, estrogen suppresses mem-

brane lipid peroxidation, apparently via the direct inherent antioxidant activity of this steroid. Indeed, estrogen can prevent the impairment of ion-motive ATPases and glucose and glutamate transporters in cortical synaptosomes, a preparation lacking nuclei.

Other possible endangering mechanisms of glucocorticoids include the suppression of the production of neurotrophic factors and the suppression of antioxidant defense mechanisms. Indeed, glucocorticoids increase the vulnerability of cultured hippocampal neurons to oxidative insults, whereas neurotrophic factors protect neurons against such insults. Amyloid β -peptide is a 40- to 42-amino-acid peptide that forms insoluble aggregates (plaques) in the brain in Alzheimer's disease; considerable evidence indicates that amyloid β -peptide may directly damage neurons and/or increase their vulnerability to excitotoxicity. Glucocorticoids significantly increase the vulnerability of hippocampal neurons to cell death induced by amyloid β -peptide. Measurements of levels of ROS in hippocampal neurons have shown that amyloid β -peptide increases peroxide accumulation and membrane lipid peroxidation and that corticosterone exacerbates such oxidative stress. Membrane lipid peroxidation is believed to play a major role in the neurodegenerative process in Alzheimer's disease by impairing the function of membrane ion-motive ATPases (Na^+/K^+ -ATPase and Ca^{2+} -ATPase) and glucose transporters.

Collectively, the available data suggest that excessive physiological and psychological stress can increase the vulnerability of at least some populations of neurons in the brain to excitotoxicity. The mechanism may involve metabolic compromise secondary to the suppression of glucose transport and/or alterations in cellular calcium homeostasis. Excitotoxic neurodegeneration involves oxidative stress and mitochondrial dysfunction, and glucocorticoids can exacerbate such oxidative stress either by directly affecting antioxidant pathways or by indirectly enhancing oxyradical production by disturbing calcium and energy homeostasis.

Although much attention has been given to the roles of glucocorticoids in exacerbating excitotoxicity, there are many other stress-induced hormones that may also influence a neuron's vulnerability to excitotoxicity. For example, corticotropin releasing hormone (CRH) and a related neuropeptide called urocortin have been shown to affect the vulnerability of neurons to oxidative, metabolic, and excitotoxic injury. CRH and urocortin act on receptors coupled to cAMP production. The activation of these receptors can protect cultured neurons against oxidative stress and excitotoxicity. Opioid peptides are another

class of stress-related hormones that can affect the excitotoxic process. For example, dynorphin and nociceptin can exacerbate excitotoxicity, whereas σ receptor ligands can have excitoprotective actions.

Anti-excitotoxic Effects of Mild Neuronal Stress

The kinds of data described so far provide strong evidence that excessive activation of the neuroendocrine stress axis is detrimental to neurons in certain regions of the brain. However, emerging findings suggest that moderate levels of stress may enhance neuronal plasticity and increase the resistance of neurons to various insults, including excitotoxic conditions. It has been repeatedly demonstrated that exposure of neurons, *in vivo* and in cell culture, to a moderate (subtoxic) level of stress can protect those neurons against a subsequent intense insult that would otherwise be neurotoxic. For example, the exposure of cultured hippocampal or cortical neurons to subtoxic levels of heat shock or excitotoxins renders them resistant to excitotoxicity. Moreover, the extent of the brain damage caused by cerebral ischemia in adult rodents is greatly reduced when the animals are subjected to a mild alchemic episode prior to exposure to severe ischemia. Such preconditioning hormesis may be mediated by the upregulation of heat shock proteins and antiapoptotic genes. The increased expression of heat shock proteins occurs in both acute neurodegenerative conditions, such as stroke and severe epileptic seizures, and in chronic neurodegenerative disorders, such as Alzheimer's disease. The available data suggest that these stress-responsive gene products serve neuroprotective functions.

In acute neurodegenerative conditions such as stroke, epileptic seizures, and traumatic brain injury, there is a robust and quite rapid increase in the expression of several different cytokines and neurotrophic factors. Considerable data suggest that this particular aspect of the stress response represents an attempt of brain cells to prevent neuronal death and promote recovery. Indeed, cell culture and *in vivo* studies have shown that the administration of some neurotrophic factors (e.g., basic fibroblast growth factor, nerve growth factor, BDNF, and insulin-like growth factors) and cytokines (e.g., tumor necrosis factor, TNF) can protect neurons against excitotoxic, metabolic, and oxidative insults. An example of a stress-responsive signaling pathway that increases neuronal resistance to excitotoxicity involves the activation of the transcription factor NF- κ B by intercellular signals such as TNF and secreted β -amyloid precursor protein (APP), as well as by increased levels

Figure 3 Excitotoxicity is a convergence point in the neurodegenerative cascades of each of the major acute and chronic neurodegenerative disorders. The genetic and environmental factors that initiate the neurodegenerative process may differ among disorders. For example, stroke is caused by the atherosclerotic occlusion of a cerebral blood vessel; Alzheimer's disease can result from mutations in the β -amyloid precursor protein or presenilins or by age-related increases in oxidative and metabolic stress, resulting in increased production of neurotoxic forms of amyloid β -peptide; and Huntington's disease is caused by polyglutamine expansions in the huntingtin gene. Despite such differences in initiating factors, each disorder results in similar neurodegenerative cascades that involve increased oxidative stress, metabolic impairment, and overactivation of glutamate receptors, resulting in excessive Ca^{2+} influx and excitotoxic cell death. Stress, dietary factors, and certain aspects of lifestyle can influence the risk of both the acute neurodegenerative conditions listed on the left and the chronic neurodegenerative disorders listed on the right. Modified from Mattson, M. P. (2003), Excitotoxic and excitoprotective mechanisms: abundant targets for the prevention and treatment of neurodegenerative disorders, *Neuromolecular Medicine* 3, 65–94.

of oxidative stress. The NF- κ B induces the expression of several cytoprotective gene products including Mn-superoxide dismutase.

A final example of a scenario in which moderate stress may be beneficial for the brain comes from recent studies of the impact of food restriction on aging of the brain and on the brain's response to metabolic and excitotoxic insults. A well-established method for increasing the life span of laboratory rodents and reducing the incidence of age-related cancers and immune alterations is to reduce their caloric intake. A decrease in levels of cellular oxidative stress appears to play an important role in the beneficial effects of food restriction. Recent studies have provided evidence that food restriction retards age-related alterations in the brain such as increases in glial reactivity and impaired performance on learning and memory tasks. With respect to interactions between stress and excitotoxicity, it was recently reported that food restriction in adult rat (alternate day feeding regimen for 2–4 months) results in resistance of hippocampal neurons to excitotoxin-induced degeneration and of striatal neurons to degeneration induced by the mitochondrial toxins 3-nitropropionic acid and malonate. Food restriction dramatically

reduced excitotoxin-induced deficits in learning and memory and also prevented the mitochondrial toxin-induced impairment of motor function. Although the mechanism underlying the beneficial effect of chronic food restriction in these rodent models of excitotoxic brain injury has not been established, it is possible that the food-restriction regimen subjects the body and brain to a moderate level of stress resulting in the upregulation of cellular defense mechanisms. In support of this scenario, data show that levels of activation of the hypothalamic-pituitary-adrenal axis and levels of heat shock proteins in some tissues are increased in food-restricted rodents.

Environmental and Genetic Risk Factors for Stress-Mediated Excitotoxic Neuronal Degeneration

An increasing number of environmental factors (e.g., diet, exercise, and exposure to toxins) and genetic factors are being identified that can affect the vulnerability of neurons to excitotoxicity (Figure 3). Several different environmental toxins have been identified that can induce nervous system damage and behavioral deficits that are remarkably similar to those seen

in human neurodegenerative conditions. As already described, kainic acid (produced by seaweed) can induce seizures and hippocampal damage reminiscent of human temporal lobe epilepsy. Similarly, domoic acid (produced by algae and concentrated in shellfish) can cause hippocampal neuron degeneration and severe memory loss. I-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) damages dopaminergic neurons by a mechanism involving, in part, the excessive activation of glutamate receptors under conditions of increased oxidative stress. The ingestion of a mitochondrial toxin (3-nitropropionic acid) produced by a mold results in selective damage to striatal neurons and motor deficits similar to those seen in Huntington's disease. An excitotoxin in the cycad seed may play a role in the widespread neurodegeneration in brains and spinal cords of individuals suffering from ALS–Parkinsonism–dementia complex of Guam. There is evidence that both the neuroendocrine stress response and neuronal stress responses can modulate the adverse effects of such excitotoxins.

Genetic defects have been identified that cause several major neurodegenerative disorders in which excitotoxicity is believed to play a role. For example, mutations in APP and the presenilins (PS-1 and PS-2) are responsible for some cases of early-onset autosomal-dominant familial Alzheimer's disease. Mutations in APP may render neurons vulnerable to age-related metabolic and oxidative stress by altering the proteolytic processing of APP in a manner that increases the production of neurotoxic amyloid β -peptide and decreases the levels of a neuroprotective secreted form of APP. Presenilin mutations appear to place neurons at risk by perturbing calcium regulation in the ER, which, in turn, leads to enhanced oxidative stress and mitochondrial dysfunction when neurons are subjected to metabolic and excitotoxic insults. Glucocorticoids have been shown to exacerbate the neurodegenerative process initiated by amyloid β -peptide and may also interact with presenilin mutations to disturb neuronal calcium homeostasis. Conversely, estrogen protects neurons against the death-enhancing effects of PS-1 mutations.

ALS, a disease in which the lower motor neurons degenerate, is believed to involve increased oxidative stress and excitotoxicity. Mutations in the antioxidant enzyme Cu/Zn-superoxide dismutase are responsible for some cases of inherited autosomal-dominant ALS. Huntington's disease is a genetic disorder in which the aberrant gene (called huntingtin) exhibits expansions of a trinucleotide repeat encoding the amino acid glutamine. Although it has not been established how the trinucleotide repeats promote the degeneration of

striatal neurons, available data suggest an alteration that increases neuronal vulnerability to excitotoxicity.

In each of these genetic neurodegenerative disorders, the defective gene is widely expressed in various cell types throughout the body and nervous system. The available data suggest that a major reason neurons are selectively vulnerable in these disorders is because of their high metabolic demands and unique vulnerability to excitotoxicity. For the same reason, various extrinsic and endogenous stressors (including the aging process itself) can have profound effects in promoting excitotoxic neuronal degeneration.

Glossary

<i>Acute exercise</i>	A single session or bout of exercise.
<i>Aerobic activities</i>	Activities using the large muscle groups at mild to moderate intensities that permit the body to use oxygen to supply energy and to maintain a steady state for more than a few minutes. Examples include walking, jogging, swimming, and cycling.
<i>Anaerobic activities</i>	Activities using the muscle groups at high intensities that exceed the body's capacity to use oxygen to supply energy and that create an oxygen debt by using energy produced without oxygen. Examples include weight lifting and sprinting.
<i>Cardiorespiratory endurance</i>	The ability to continue or persist in strenuous tasks involving the large muscle groups for extended periods of time. The ability of the circulatory and respiratory systems to adjust to and recover from the effects of whole-body exercise or work. Also called aerobic endurance.
<i>Chronic exercise</i>	Exercise usually performed for 6–8 weeks or longer.
<i>Physical fitness</i>	A dynamic state of energy and vitality that enables one to carry out daily tasks, to engage in active leisure-time

pursuits, and to meet unforeseen emergencies without undue fatigue.

The impact of exercise training and improved physical fitness on stress including psychological, social, and physical functioning has received considerable attention, particularly in light of the increasing popularity of exercise as a leisure-time activity. Exercise may vary by mode (i.e., kind of exercise), duration, intensity, and frequency. There are two primary kinds of exercise that are classified on the basis of how energy to perform work is derived: aerobic exercise and anaerobic exercise. Most of the research on stress and exercise has focused on the psychological benefits of chronic aerobic exercise (i.e., exercise performed several times per week over a period of weeks or months).

General Methodological Issues

The empirical evidence for the relation between exercise and stress is derived from multiple disciplines (psychology, exercise physiology, psychophysiology, physical therapy, etc.) that may approach the topic from different perspectives and conceptual models. The type of experimental design (e.g., cross-sectional, longitudinal, or interventional) is an important consideration. Cross-sectional studies typically compare stress responses of fit versus unfit groups, athletes versus nonathletes, or people who engage in one form of exercise with individuals who engage in different exercise (e.g., joggers vs. weight lifters). Because of the correlational nature of cross-sectional studies, however, causal attributions are not possible. Longitudinal designs also are correlational and typically follow subjects who engage in different kinds of exercise over time. Interventional studies typically involve the assignment of individuals to either exercise or nonexercise conditions and compare the groups over time. Random group assignment is necessary to

attribute differences in outcomes to the intervention. Control groups, another important design consideration, should be matched as closely as possible to the experimental group on nonspecific variables (e.g., demand characteristics, experimental contact, and social support). Other important issues include methods for assessment of aerobic fitness operationally and procedures for measuring stress. Although there are a number of ways to measure aerobic fitness (e.g., questionnaires, 10-min walk/run, step test, and treadmill test), the most precise assessment of aerobic fitness involves a multistage maximal exercise test on a treadmill or cycle ergometer with direct measurements of oxygen consumption. Stress responses can be measured by self-report questionnaires or may be measured physiologically. For example, heart rate and blood pressure are commonly used measures of stress response, most likely due to their ease of measurement and sensitivity to differences in fitness levels. The selection of laboratory stressors is important because the stressor must elicit a strong psychophysiological or subjective response that is measurable and potentially modifiable. The most commonly used stressors include cognitive tasks such as mental arithmetic, the Stroop Test, or public speaking; performance tasks such as the Mirror Trace Task or video games; or physical tasks such as the hand dynamometer test or cold-pressor test. Ideally, a number of stressors, varying in intensity and patterns of physiological response, may be used most effectively in identifying changes in stress reactivity. Other physiological indices of stress, and particularly of sympathetic nervous system activation, such as secretion of urinary catecholamines, also may be used to provide an overall physiological index of stress. Adherence is another important issue in exercise research, particularly because of the high rates of nonadherence. It has been estimated that more than 50% of people who initiate an exercise program will terminate the program within the first several months. This issue is especially relevant in light of the fact that exercise must be maintained in order to achieve its physical and mental health benefits. Such strategies for improving compliance have been the focus of much research.

Cardiorespiratory Responses to Exercise

The ability to engage in physical exercise depends on the ability of the circulatory system to deliver oxygen to exercising muscles. When exercise is initiated, the heart rate is increased, first by withdrawal of the parasympathetic nervous system and then by the activation of the sympathetic nervous system. Stroke volume (i.e., the amount of blood pumped from the heart with each contraction)

increases, along with cardiac output. The heart rate may increase up to threefold the resting values, and the stroke volume may increase by 15%. Systolic blood pressure typically increases proportional to exercise intensity, whereas diastolic blood pressure normally remains unchanged or may increase slightly.

During exercise, there is a gradual increase in oxygen demand by the exercising muscles. As the oxygen delivered in the arterial blood is used by the muscle, the oxygen level in the returning venous blood is decreased, resulting in a widening of the arterial-venous oxygen difference. These changes in oxygen demand and use are reflected by increased oxygen consumption (VO_2). Repeated bouts of aerobic exercise produce training effects, increased maximal VO_2 and lowered heart rate at rest and during submaximal exercise workloads.

Psychological Responses to Exercise

The psychological effects of chronic exercise on personality functioning and mood have been widely studied. Although there do not appear to be any specific personality types associated with specific kinds of exercise (e.g., joggers vs. weight lifters), active individuals tend to have higher self-esteem and greater self-confidence than sedentary individuals. Athletes (with the exception of marathon runners) are more likely to be extroverted and less neurotic than nonathletes. Athletes also tend to have less anxiety, depression, anger, and fatigue and more vigor than their nonathletic counterparts. Interventional studies have shown exercise to improve self-concept, self-esteem, and self-efficacy.

The type A personality is a behavioral complex that has been shown to be associated with increased risk for premature cardiovascular disease. Type A individuals are more competitive, hard driving, impatient, and aggressive than their more easy-going type B counterparts. Although type As are not more likely to be physically active than type Bs, type A behavior has been shown to be reduced by exercise training, including both jogging and weight lifting.

There is increasing evidence that chronic exercise results in improved mood and psychological well-being. Cross-sectional studies have demonstrated that active individuals report less anxiety and depression and better emotional well-being relative to their sedentary counterparts. Longitudinal studies also have reported that negative mood states can be reduced with regular exercise. A number of interventional studies have demonstrated that increasing physical activity results in reduced levels of stress, anxiety, and depression. It has been shown that sedentary individuals are more likely to be depressed

than active people and that individuals who increase their activity levels have no greater risk for depression than people who maintain higher activity levels. Moreover, active people who become sedentary may increase in their risk for depression by 50%.

Studies also have investigated the relation between exercise and physiological stress responses. A number of cross-sectional studies have demonstrated that physically fit or physically active individuals exhibit lower cardiovascular responses to physical and mental stressors compared to unfit or sedentary individuals. Because regular exercise results in physiological adaptations that may affect responses to psychological challenges, interventional studies also have examined the effects of exercise training on cardiovascular and neuroendocrine responses to laboratory stressors such as mental arithmetic and public speaking. The results of these studies have shown that heart rate and blood pressure responses to these mental stressors are attenuated after 12–16 weeks of exercise and that aerobic exercises (e.g., jogging or biking) are generally more effective than anaerobic exercises (e.g., strength training) in reducing psychophysiological stress responses. The extent to which these altered physiological responses to laboratory tasks generalize to stressors during daily life, however, has not been examined.

The acute effects of exercise also have received attention. It has been hypothesized that the chronic adaptations associated with exercise result from the accumulated effects of individual bouts of exercise over time. Consequently, investigators also have examined the acute effects of exercise on various measures of stress. Studies of the short-term effects of exercise provide evidence for the mood-enhancing benefits of acute aerobic exercise. Correlational and experimental studies have demonstrated reduction in depression, anxiety, tension, and anger following a single bout of exercise. However, the intensity level at which exercise is beneficial is unclear. Some studies have found benefits from low- to moderate-intensity exercise and negative consequences of high-intensity exercise (e.g., greater increases in tension and fatigue); however, other studies have demonstrated reductions in psychological tension following moderate to intense exercise but not mild exercise. Acute aerobic exercising also has been shown to attenuate cardiovascular responses to laboratory stressors in several studies, although the data are too limited to draw definite conclusions.

Health Risks of Exercise

The potential adverse effects of exercise are important considerations in evaluating exercise as a stress-management technique. It is important to note that

Table 1 Stress-related changes with chronic aerobic exercise

	<i>Change</i>
<i>Physiological</i>	
Resting heart rate	↓
Resting blood pressure	↓
Catecholamines	↓
Vagal tone	↑
<i>Psychological</i>	
Anxiety	↓
Depression	↓
Self-esteem	↑
<i>Psychophysiological</i>	
Blood pressure	↓
Heart rate	↓
Catecholamines	↓

although exercise is widely regarded as a beneficial activity, exercise may be associated with untoward events in susceptible individuals. However, even in cardiac patients, the potential adverse effects of exercise such as arrhythmias and myocardial infarction are relatively rare and occur in less than 1 of 10 000 exercise tests and at a rate of less than 1 per 100 000 h of exercise training. Minor muscle aches and joint pains are common – either as a result of overuse or acute trauma – but are usually self-limited. Major orthopedic problems are very uncommon in supervised exercise settings, but may be more common in unsupervised programs or in individuals who fail to comply with exercise prescriptions. The annual rate of exercise-related injury in adults is roughly 10%, with only 5% requiring medical care. These injuries often result from a sudden unexpected trauma, such as twisting an ankle. Proper warm-up and stretching are useful preventative measures. Overuse injuries, on the other hand, are a result of chronic, accumulated stress on the musculoskeletal system. This type of injury is more common in high-impact, weight-bearing activities such as jogging and includes such problems as tendonitis, stress fractures, and ruptured disks in the lower back. Gradual progression of exercise, attention to environmental factors (e.g., heat and humidity, altitude), and the use of proper equipment all serve to reduce the risk of injury.

Exercise addiction is a term related to overuse and is generally described as an addiction of psychological and/or physiological nature to regular physical activity, characterized by withdrawal symptoms after 2 to 3 days without exercise. Although exercise as a compulsive behavior has been characterized as a positive addiction that promotes well-being, the potential for abuse has been recently recognized. Individuals may experience depression, anxiety, and irritability if they are unable to exercise. There is some evidence that exercise addiction can have an adverse impact on

interpersonal and occupational functioning, as well as on self-esteem. There is also some suggestion of overlap between excessive exercise and eating disorders. Obligatory running in men, for example, has been likened to anorexia nervosa in women. However, there is little empirical support for the notion that either the etiology or level of psychopathology is comparable between anorexics and compulsive exercisers. Eating disorders also may be more prevalent among women, particularly among participants in certain forms of exercise (e.g., ballet, gymnastics, and figure skating).

Mechanisms

The mechanisms by which exercise reduces stress are not known. A number of psychological mechanisms have been proposed, including increased self-efficacy, a sense of mastery, positive thoughts, distraction from negative thoughts, and enhanced self-concept, which in turn can lead to improved mood. Exercise may also be a form of meditation that triggers a more relaxed state or a form of biofeedback that teaches people to regulate their autonomic arousal. Exercise may also be associated with social reinforcement. There is not, however, definitive evidence to support any one explanation.

A number of biological mechanisms also have been suggested, although there is no consensus as to the precise mechanism whereby stress is reduced. There are data to suggest that the antidepressant effect of chronic exercise may be mediated by increased central norepinephrine neurotransmission. Changes in the hypothalamic-pituitary-adrenocortical axis may also be related to improved mood due to the lessened cortisol response to submaximal exercise following exercise training. Increased levels of β -endorphins may also contribute to the antidepressant effects of exercise. However, most studies have failed to employ adequate

methodologies to accurately measure circulating endorphin levels in the brain.

Summary and Future Directions

Both acute exercise and chronic exercise have been shown to reduce stress responses measured behaviorally, psychologically, and physiologically (see [Table 1](#)). Research efforts are currently directed at identifying those individuals who are most likely to benefit from exercise, at examining the mechanisms by which exercise reduces stress, and at developing strategies for improving long-term adherence to exercise and for motivating people to initiate exercise behavior.

Future Perspectives

Figure 1 Molecular mechanisms of GR action on gene expression. Transactivation: after binding to corticosteroids, GRs translocate from the cytoplasm to the cell nucleus and bind to glucocorticoid-responsive elements (GREs) on the DNA, thereby influencing the transcription rates of target genes. Transrepression: corticosteroid-activated GRs bind to other transcription factors (such as AP-1), inhibiting their transcriptional actions.

Glossary

<i>Corticosteroids</i>	Steroid hormones secreted at high levels during stress that regulate carbohydrate metabolism and influence the inflammatory response and cognition, mood, and behavior. Also known as glucocorticoids.
<i>Glucocorticoid receptor (GR)</i>	An intracellular receptor that binds corticosteroids and then translocates to the nucleus, where it influences gene expression.
<i>Hippocampus</i>	A complex neural structure (shaped like a sea horse) consisting of gray matter and located on the floor of each lateral ventricle; intimately involved in motivation and emotion as part of the limbic system; has a central role in the formation of memories.
<i>Large-scale gene expression profiling</i>	A general name for molecular biological methods aimed at measuring expression levels of large numbers of genes (>100–30,000) simultaneously. Also known as transcriptomics or (pharmaco)genomics.
<i>Limbic system</i>	A group of interconnected deep brain structures, common to all mammals, and involved in olfaction, emotion, motivation, behavior, and various autonomic functions.
<i>Mineralocorticoid receptor (MR)</i>	An intracellular receptor that binds aldosterone and then translocates to the nucleus, where it influences gene expression. This receptor, which is colocalized with glucocorticoid receptor in several limbic brain structures, also has a high affinity for corticosteroids.

Introduction

The hypothalamic-pituitary-adrenal (HPA) axis is involved in regulation of stress responses in the organism. Under normal conditions, the adrenals secrete basal concentrations of corticosteroids into the bloodstream in a circadian manner. When the organism experiences a stressor, the activity of the HPA axis increases, which results in increased concentrations of corticosteroids. These corticosteroids (CORT) target many organs, exerting effects on blood glucose levels and immune function. Furthermore, corticosteroids are able to pass the blood–brain barrier, affecting brain functions such as cognition, behavior, and mood.

This article focuses on the effects of corticosteroids on gene expression in brain. These stress hormones have a profound effect on brain function. Moreover, exposure to chronic stress can precipitate the onset of central nervous system disorders such as depression.

Corticosteroids Modify Gene Expression

There are two endogenous receptors for CORT that are colocalized in several limbic brain structures such as the hippocampus and amygdala. The mineralocorticoid receptor (MR), which is expressed at high levels in the hippocampus, has a high affinity for its ligand and is already occupied under basal concentrations. The glucocorticoid receptor (GR) is ubiquitously expressed, has a tenfold lower affinity, and becomes occupied during rising concentrations of corticosteroids, for instance, during stress.

Both MR and GR belong to the superfamily of ligand-regulated nuclear receptors and are able to modify gene expression via two different mechanisms: (1) transactivation, in which the receptors bind to glucocorticoid-responsive elements (GREs) on the DNA and influence the transcription rate of the target genes, and (2) transrepression, in which the receptors interact with other transcription factors (such as activator protein-1 [AP-1] and nuclear factor- κ B [NF- κ B]), thereby inhibiting their transcriptional actions (Figure 1).

Effects of Stress on the Hippocampus

One of the major targets in the brain is the hippocampus, a structure that plays a crucial role in learning, memory, emotion, and regulation of the stress system. Several aspects of hippocampal cell function, such as neurotransmission and energy metabolism, are under the tight control of corticosteroids.

MR and GR, which are colocalized in hippocampal neurons, exert differential effects on hippocampal cell function. For instance, under low, basal concentra-

Figure 2 Outline for a large-scale gene expression profiling strategy. In order to elucidate the molecular mechanisms underlying the corticosteroid-mediated effects on the hippocampal phenotype, large-scale gene expression profiling techniques are used to assess corticosteroid-responsive genes. Candidate genes are selected and hypotheses are generated as to how these genes may play a role in the observed effects of corticosteroid on the hippocampus. These hypotheses are then tested in functional studies.

tions in which only MR is occupied, neuroexcitability in hippocampal neurons is high, whereas under stress conditions, in which both MR and GR are occupied, neuroexcitability is low. Thus, MR is involved in maintenance of neuronal excitability and basal activity of the stress system, while GR activation results in reduced hippocampal output and is involved in negative feedback to restore homeostasis. Inadequate corticosteroid input as well as chronic occupation of GR results in degeneration of hippocampal neuronal circuits, accompanied by deficits in cognition and maladaptation to stress. A balanced activation of MR/GR is therefore an important determinant of neuronal excitability, stress responsiveness, and neuronal health.

Since (1) MR and GR are able to modify gene expression and (2) the majority of the effects of corticosteroids on hippocampal cell function develop in a delayed manner, it can be hypothesized that changes in gene expression underlie these CORT-induced effects. Therefore, by determining the CORT-induced changes in gene expression, the molecular mechanisms responsible for the actions of corticosteroids can be investigated. This entails measuring the expression levels of thousands of genes simultaneously, known as large-scale expression profiling, transcriptome analysis, or pharmacogenomics.

Large-Scale Gene Expression Profiling

In [Figure 2](#) the general outline for a large-scale gene expression profiling strategy is depicted. Instead of starting with a hypothesis, this strategy raises the question which genes are regulated by the hormone. Therefore, this type of research can be described as question-driven as opposed to hypothesis-driven research, and its primary goal is to generate gene expression profiles. When these profiles are established, candidate genes can be selected and hypotheses are generated as to how the selected candidate genes may play a role in the observed effects of corticosteroids on the hippocampal phenotype. Finally, these hypotheses are tested in functional studies using *in vitro* systems such as cell lines or *in vivo* systems such as transgenic animals.

Large-scale gene expression profiling can be performed in a number of ways. Two of the more commonly used techniques are serial analysis of gene expression (SAGE) and DNA microarrays.

In SAGE, gene expression profiles are established by sequencing and counting 10-base-pair-long SAGE tags that are derived from a defined position within the 3'-untranslated region of each transcript. By sequencing and counting sufficient transcript-specific tags, a representative expression profile is obtained of

Figure 3 Serial analysis of gene expression (SAGE). In SAGE, 10-bp-long tags are generated from mRNA pools of different experimental treatment groups (for instance, corticosteroid-treated [+CORT] and control [-CORT]) groups). These mRNA-specific tags are ligated to produce concatemers, which are cloned and sequenced. By counting the tag abundancies, mRNA expression levels can be estimated and compared between the different experimental groups.

a tissue under conditions of interest, for example, after hormone treatment (Figure 3).

DNA microarrays are glass microscope slides or silica chips on which a large number of DNA sequences representing a part of each transcript are deposited at a very high density. Depending on the type of microarray, the number of represented transcripts can range from 1000 to more than 20 000. Expression levels of each transcript are measured by hybridizing labeled RNA from a tissue of interest to the microarray, thus generating a hybridization signal (mostly fluorescent) that is a measure for the expression level of the corresponding transcript.

The use of DNA microarrays has been described as following a closed expression profiling strategy, since only the expression of a predefined set of genes (i.e., the sequences that are represented on the microarray) is profiled. In contrast, by using SAGE, no selection of transcripts is made beforehand; thus, this method can be considered an open expression profiling strategy.

Model Systems of Stress

The first step of an expression profiling strategy is the choice of the model system. Several model systems in which corticosteroid levels are pharmacologically manipulated can be used, although one must be aware

that this only represents the hormonal part of the stress response and is not the same as stress. For instance, surgically removing the adrenals from rats results in complete absence of endogenous corticosteroids and lack of hippocampal MR and GR occupancy. Adrenalectomized rats can be further manipulated by (1) replacing them with low concentration corticosteroid-secreting pellets, resulting in occupancy of hippocampal MRs, and (2) administering high-concentration corticosteroid injections in order to additionally occupy hippocampal GRs. After isolating the hippocampi from these animals, gene expression profiles can be generated. Additionally, *ex vivo* hippocampal slices, which are derived from isolated hippocampi and are kept alive in carbogenated buffer, have also been used as a model to study the effects of corticosteroids on gene expression. In these slices, corticosteroid receptors can be directly activated by adding the hormone to the solution, thereby circumventing peripheral effects of injections into animals and removing the influence of projections from other brain areas to the hippocampus.

Another way of looking at the effects of stress on gene expression is to subject intact animals to a stressor, causing physiological activation of their HPA axis and a rise in plasma CORT levels. Several stress paradigms have been described in the literature, both for

acute stress and for chronic stress. For example, placing a rat or mouse in a novel environment is sufficient to elicit a stress response, or placing a rat on top of the cage of a mouse will give rise to a stress response in the mouse. Purely physical stressors, such as cold stress or shaking stress, can be distinguished from psychological stressors such as psychosocial defeat and chronic unpredictable stress, in which experimental animals are subjected to a variety of different stressors in an unpredictable manner over several weeks.

A disadvantage of the physiological approach is that it can be difficult to control for interindividual differences in HPA response. Pharmacological manipulation of CORT levels in combination with a relevant psychological stressor may therefore be a good choice, depending on the focus of the study.

Stress-Responsive Gene Patterns in Brain

Different combinations of model systems and gene expression profiling techniques have been applied to analyze stress or corticosteroid-dependent changes in gene expression in brain. The vast majority of these studies focus on the hippocampus, because the activity of hippocampal neurons is modulated by elevated corticosteroid levels and it is the region with the highest expression of CORT receptors in the brain. Most of the studies have focused on GR-dependent gene expression. So far, not much is known about the genes regulated by MR as well as its molecular mode of action. It has been shown, using SAGE to analyze CORT-dependent gene expression in hippocampus of rats in which either MR or both MR and GR were occupied by pharmacological manipulation of CORT levels, that MR and GR activate or repress distinct yet partially overlapping sets of genes. This suggests that largely different signaling pathways are involved in maintenance of the basal activity of the stress system (MR dependent) and in the stress response (GR dependent).

In a study in tree shrews subjected to chronic psychosocial stress, reduced expression of four genes involved in cell differentiation in response to stress was found. This finding is in agreement with previous findings that this chronic psychosocial stress paradigm in tree shrews leads to structural alterations in hippocampal neurons such as dendritic retraction and impaired neurogenesis.

In a chronic psychosocial stress study performed in mice selected for attack latency (long attack latency [LAL]), hippocampal expression profiles were analyzed using DNA microarrays after 25 days of continuous sensory contact with an aggressive short attack latency (SAL) male. LAL mice but not SAL

mice have been shown to display symptoms of chronic stress, such as increased CORT levels, decreased body weight, and lower hippocampal MR expression, using this paradigm. Interestingly, only downregulated genes were observed in response to this chronic psychosocial stress paradigm. The identified genes encoded a heterogeneous group of different proteins, the majority showing a subtle (less than twofold) downregulation. Several transcripts were identified to be involved in regulation of NF- κ B signaling, suggesting that NF- κ B may be involved in stress-induced functional changes in hippocampal neurons, thereby increasing their vulnerability.

Another study using *ex vivo* hippocampal slices investigated the gene expression response in time following GR activation. This revealed that corticosteroid effects are subtle and transient, with several subsequent waves of gene expression occurring after a single corticosteroid-pulse. Furthermore, within 5 h after activation of GR the gene expression response was comparable to the control group (non-activated GR).

Taking all these studies together, a general conclusion can be drawn that CORT-dependent gene expression encompasses a large variety of functional gene classes involved in energy metabolism, cell adhesion, synaptic transmission, oxidative stress, metabolism, neurogenesis, the cell cycle, and structural plasticity. In addition, the observed responses in hippocampus are subtle in magnitude. Therefore, it is very difficult to conclude which signaling pathways in the brain are most important and most profoundly affected by stress. It appears that corticosteroid stress hormones confer a pleiotropic signal to the neuron, affecting its excitability, connectivity to other neurons, metabolic rate, strength of its synaptic connections, differentiation from newborn neuron into mature neuron, and its vulnerability to metabolic damage. What exactly this means for neuronal function and vulnerability of the individual for stress-related brain disorders remains to be clarified.

The current expression profiling methodology has several limitations. It is still not possible today to perform genome-wide screening for genes regulated by stress due to the fact that annotation of the rat and mouse genome is not fully completed. Furthermore, so far low abundant genes such as neurotransmitter receptors and neurotrophic factors have been underrepresented due to sensitivity issues. Both these factors have also contributed to the currently incomplete picture of the effects of stress and corticosteroid stress hormones on hippocampal gene expression.

Future Perspectives

Since the hippocampus consists of many different cell types, it can be expected that by profiling whole hippocampus, CORT-dependent changes in expression that occur in a specific subpopulation of cells will be diluted to undetectable levels. Therefore, the feasibility of reducing the complexity of the tissue by using laser-microdissected hippocampal subregions has recently been evaluated. A high degree of differential expression between two different hippocampal subregions was identified, indicating that by isolating specific subregions of the hippocampus, detection efficiencies of transcripts with a subregion-specific expression or regulation may be improved. This type of approach combined with use of more genome-wide DNA microarrays and better bioinformatics tools to analyze this type of complex expression data should extend our knowledge on stress-dependent gene patterns in brain.

In conclusion, the application of large-scale expression profiling strategies has revealed a number of interesting candidate genes that may underlie some of the effects of corticosteroids on hippocampal cell function. Additionally, the use of laser-microdissected hippocampal subregions for expression profiling may increase the detection of low abundant genes, resulting in a more refined view on corticosteroid-responsive genes.

CONTENTS BY SUBJECT AREA

ANIMAL STUDIES AND MODELS

- Animal Models (Nonprimate) for Human Stress
- Circadian Rhythms, Effects of Prenatal Stress in Rodents
- Fish, Stress in
- Immobilization Stress
- Pre-pulse inhibition
- Primate Hierarchies and Personality
- Primate Models, Behavioral-Immunological Interactions
- Primate Models, Cardiovascular Disease
- Primate Models, Overview
- Primates: Rearing and Effects of Stress on Primate CNS Function
- Sex-Specific Effects of Early Social Stress in Mammals: a Study in Guinea Pigs

CONFLICT, WAR, TERRORISM

- Chemical Warfare
- Gulf War Syndrome, Psychological and Chemical Stressors
- Hiroshima Bombing, Stress Effects of
- Holocaust, Stress Effects of
- Impact of Terrorism on the Development of Mental Health Symptoms
- Korean Conflict, Stress Effects of
- Lockerbie Air Crash, Stress Effects of
- Northern Ireland, Post Traumatic Stress Disorder in
- Nuclear Warfare, Threat of
- Oklahoma City Bombing, Stress Effects of
- Persian Gulf War, Stress Effects of
- Prisoners of War
- 9/11, Religion and Stress
- Suicide Terrorism, Genesis of
- Terrorism
- Torture

- Traumatic Stress and Posttraumatic Stress Disorder; the Israeli Experience
- Vietnam Veterans, Postwar Experiences and Health Outcomes
- War Stress in the Former Yugoslavia
- War, Suicide and Sacrifice

DISASTERS

- Airline Accidents
- Chernobyl, Stress Effects of
- Disasters and Mass Violence, Public, Effects of
- Disaster Syndrome
- Earthquakes, Stress Effects of
- Floods, Stress Effects of
- Hurricane Katrina Disaster, Stress Effects of
- Motor Vehicle Accidents, Stress Effects of
- Three Mile Island, Stress Effects of

DIURNAL, SEASONAL AND ULTRADIAN RHYTHMS

- Circadian rhythm effects on cardiovascular and other stress-related events
- Circadian Rhythms, Genetics of
- Night Shiftwork
- Seasonal Changes in Stress Responses
- Seasonal Rhythms
- Sleep Loss, Jet Lag, and Shift Work
- Sleep, Sleep Disorders, and Stress
- Ultradian Rhythms

DRUGS (EFFECTS)

- Alcohol, Alcoholism and Stress: A Psychobiological Perspective
- Drug Use and Abuse
- Interactions between Stress and Drugs of Abuse
- Opioids

DRUGS (TREATMENT)

- Antipsychotic Drugs and Stress
- Anxiolytics
- Benzodiazepines
- Beta-Adrenergic Blockers
- Pharmacological Treatments of Stress
- Selective Serotonin Reuptake Inhibitors (SSRIs)
- Stress and Anxiety: treatment with 2nd generation antipsychotic drugs

GENERAL CONCEPTS AND MODELS

- Alarm Phase and General Adaptation Syndrome
- Allostasis and Allostatic Load
- Behavior, Overview
- Conservation of Resources Theory
- Control and Stress
- Demand–Control Model
- Effort–Reward Imbalance Model
- Environmental Factors
- Evolutionary Origins and Functions of the Stress Response
- Fight-or-Flight Response
- Instinct Theory
- Life Events Scale
- Psychological Stressors, Overview
- Remodelling of neuronal networks by stress
- Selye, Hans
- Stress, Definitions and Concepts of
- Stress Effects, Overview
- Stress System Balance Hypothesis
- Stress, Beneficial Effects of

GENETICS AND GENOMICS

- Circadian clock genes as modulators of sensitivity to genotoxic stress
- Corticosteroid Receptor Genes: Functional Dissection in Mice
- Corticotropin Releasing Factor Receptor Deficiency in Mice
- Drosophila Genes and Anoxia
- Expression Profiling of Stress Responsive Gene Patterns
- Gene Environment Interactions in Early Development
- Genetic Factors and Stress
- Genetic Polymorphisms in Stress Response
- Genetic Predispositions to Stressful Conditions
- Genetic Testing and Stress
- Genetic variation of HPA axis activity and function in farm animals
- Glucocorticoid Receptor Mutant Mice as Models for Stress-Induced Affective Disorders

- Glucocorticoid Receptor Mutations and Polymorphisms
- Mineralocorticoid Receptor Polymorphisms
- Neuroticism Genetic Mapping of
- Neuroticism Response to Stress, Genetic Mapping of Mice
- Serotonin Transporter Genetic Modifications
- Strain Differences in Stress Response in Rodents
- Stress and CNS Arousal; Genomic Contributions

HUMAN COGNITION, EMOTION AND BEHAVIOR

- Adolescence
- Aggression
- Aggressive Behavior
- Aging and Psychological Stress
- Anger
- Anxiety
- Bereavement
- Burnout
- Captivity, Adaptation to
- Captivity, Recovery from
- Caregivers, Stress and
- Childbirth and Stress
- Cognition and Stress

PREFACE TO FIRST EDITION

“Stress” remains one of the most frequently used but ill-defined words in the English language. Stress is a phenomenon that has quite different meanings for the politician, social scientist, physician, nurse, psychotherapist, physiologist, molecular biologist, and perhaps you and me. This diversity of meanings was one impetus for creating the *Encyclopedia of Stress*, the aim being to derive a definition of stress from a variety of expert descriptions. The second impetus was the obvious need for an up-to-date compendium on one of the most important social, medical, and psychological phenomena of our age. We were fortunate in attracting stars for our Editorial Board and a set of most distinguished contributors for the 400 or so entries—indeed, the list of contributors is a Who’s Who in stress research.

We anticipate that the diversity of our readers will equal the diversity of the topics covered. They will find that the coverage of the Encyclopedia extends well beyond the general adaptation theory of Hans (Janos) Selye and the fight-or-flight response of Walter Cannon. Nevertheless, the general principles annunciated by these two great pioneers in the field still underpin our understanding of the biology of the stress phenomenon. That is, stress is a real or perceived challenge, either endogenous or exogenous, that perturbs body equilibrium or “homeostasis.” The stressor may range from overcrowding, traffic congestion, violence, bereavement, redundancy, or unemployment to physical, chemical, biological, or psychological insults. Whether the person can adapt to or cope with the stress will depend on the nature and severity of the stressor and the person’s physical and mental state, which in turn depends on genetic, experiential, social, and environmental factors. These issues are discussed in depth in the Encyclopedia, as are the mechanisms of coping and the impact of stress on health and predisposition to diseases such as

cancer, infection, rheumatoid arthritis, heart disease, high blood pressure, and mental disorder.

Aggression remains a hallmark of human behavior, even as we move into the third millennium, and so the Encyclopedia covers several topical areas that have only recently been analyzed systematically. These include war and specific wars, posttraumatic stress disorder (PTSD; formerly thought of vaguely as “shell shock”), rape, torture, marital discord and spousal abuse, and the Holocaust. In tackling these topics we accept that our entries may not include all the nuances that are necessary for a full understanding of what these phenomena are all about and described so graphically and sensitively in Tolstoy’s *War and Peace* or Pat Barker’s monumental *Regeneration* trilogy on the horrific psychological traumas of the First World War. Nevertheless, an important start has been made in that we now accept that PTSD is not just a lack of “bottle” (courage or “guts”), but rather a syndrome that needs to be and can be understood within the framework of medicine and psychology.

Biologically, the stress response reflects a set of integrated cascades in the nervous, endocrine, and immune defense systems. As in most areas of biology, molecular genetics has made a significant difference in the precision with which we now understand the physiopathological processes of the stress response. And so the adage formerly applied to diabetes mellitus may now apply equally to stress: “Understand stress and you will understand medicine.”

In summary, we hope that this first *Encyclopedia of Stress* will indeed define the phenomenon and at the same time provide a valuable source of information on a phenomenon that affects us all. In setting out on this adventure we were aware that there is nothing new under the sun and that stress has been around since the first biological particles, bacteria, or even viruses competed for the same mechanisms of replication.

There is a tendency for each generation to imagine that stress and its untoward effects are uniquely harsh for them, but it is not this misconception that underlies this work. Rather, the stress of “stress” itself—the massive accumulation of knowledge—made it seem propitious to bring the information together in a systematic manner that allows ready access to all who need or wish to understand the phenomenon.

The idea of producing this Encyclopedia was conceived at an Academic Press reception in San Diego held in conjunction with the annual meeting of the Society for Neuroscience in 1996. I am deeply indebted to Erika Conner for enabling conversion of the idea to a concept and then a project and to

Jennifer Wrenn, Christopher Morris, and Carolan Gladden, all of Academic Press, for their enthusiasm, encouragement, and herculean efforts that converted the concept into a reality. For giving generously of their intellect, expertise, sound advice, and unstinting work, I am greatly indebted to my friends and colleagues on the Editorial Board, who made the project such a satisfying experience. To all our contributors go our profound thanks for taking time out from wall-to-wall schedules to produce their entries, which together have made this Encyclopedia.

PREFACE TO THE SECOND EDITION

The popularity of the first edition of the Encyclopedia of Stress, the several major stressful conflicts that have occurred since 1999, and the significant advances in our knowledge of stress prompted the production of this second edition. In addition to more than 140 new articles, most of the original 400 first edition articles have been updated for the second edition to reflect, for example, advances in our understanding of corticotropin releasing factor (CRF) and urocortin receptors, ideas about the role of central CRF in the overall control of the psychological/mental as well as neuroendocrine response to stress, and the novel discoveries of the complex neuropeptide regulation of hunger and satiety. The effects of maternal and perinatal stress on subsequent body development and function in the adult, the adverse effects of stress on brain (and particularly hippocampal memory function), the role of the amygdala in fear and aggression, and the role of stress in the etiology of obesity and the metabolic syndrome all feature prominently in this new edition. 9/11 and the many new conflicts since 1999 have engendered new articles on terrorism, suicide bombers and their effects, as well as a retrospective on previous human apocalypses such as Hiroshima. Coverage of the whole field of post traumatic stress disorder (PTSD) has been expanded, reflecting the greater recognition and understanding of PTSD, and possibly related disorders such as *combat fatigue* and *burnout*. Stress and depression and anxiety, already touched on in the first edition, now feature prominently. On the conceptual side, *allostasis* (modified from Hans Selye's *heterostasis*), or stability through centrally regulated change in physiological set points, receives greater emphasis than it did in the first edition.

Overall, our understanding of stress mechanisms in the human has benefited from two major quantum leaps in technology. First, the advances in molecular genetics and genomics and sequencing of the human

genome (published after the first edition had appeared) have increased the rigor and precision of our understanding of the molecular neurobiology of stress. Thus, new to the second edition are a series of articles on the genetic factors that play a role in susceptibility to stress and in various components of the stress response. Secondly, functional brain imaging has enhanced our understanding of the neurobiology of stress in the human. Many of the articles in the second edition reflect the positive impact of these two advances.

Accessibility to the second edition of the Encyclopedia of Stress will be facilitated by virtue of the fact that it is published online as well as in hard copy. My profound thanks for their selfless work go to our team of distinguished authors and to my friends and colleagues on the Editorial Board. Production of the Encyclopedia would not have been possible without our colleagues at Elsevier, and in particular Bob Donaldson and Hilary Rowe whose dedication, commitment and excellent work I am pleased to acknowledge.

Note on Terminology of Corticotropin Releasing Factor/Hormone and the Catecholamines

The central nervous regulation of the anterior pituitary gland is mediated by substances, mainly peptides, which are synthesized in the hypothalamus and transported to the gland by the hypophysial portal vessels. Because these compounds are transported by the blood, the term "hormone" gained acceptance in the neuroendocrine literature. The major hypothalamic peptide involved in the stress response is the

41-amino acid corticotropin releasing factor (CRF). The Endocrine Society (USA), following convention, adopted the term corticotropin releasing hormone (CRH). However, this nomenclature has been challenged. Hauger et al. (*Pharmacol Rev* 55: 21–26, 2003), in liaison with the International Union of Pharmacology Committee on Receptor Nomenclature and Drug Classification, argued that the CRF's function extends well beyond the biology of a hormone, and that therefore it should be termed corticotropin releasing factor (CRF) rather than hormone. Since the terminology of CRF versus CRH has yet to be resolved, the two terms and abbreviations are here used interchangeably, depending on author preference.

Adrenaline and *noradrenaline* are catecholamines that play a pivotal role in the stress response. These

terms are synonymous with *epinephrine* and *norepinephrine*, respectively. Both sets of terms are used interchangeably in the endocrine, neuroendocrine and stress literature, and this principle has been adopted for the Encyclopedia. Style has depended on author preference, but wherever possible within-article consistency has been ensured.

FOREWORD

This is the second edition of the *Encyclopedia of Stress*, the three heavy volumes that first appeared in 2000 under the overall editorial guidance of George Fink. From its original coining in reference to rather unusual and unpleasant situations, the word *stress* is now quasi synonymous with *life*, i.e. modern life! This second edition of the *Encyclopedia of Stress* presents several hundreds of articles written by experts in that particular field, especially for this series, discussing, clarifying, explaining to the average-reader as well as to anyone more educated in one field or another, the extraordinary involvement of stress and our normal or abnormal reactions to it, both in our physical body and its accompanying mind. The table of contents is truly amazing, from the stress of being born to the stress of dying and so many circumstances in between, with clear presentations of the pertinent, current knowledge about them. This is truly an encyclopedia where, surely, you will find some explanation and answer to your own stresses (and those of others).

Measurement of Stressors

Stress and Disorder

Shared Stressors and Disorders in Families

Transmission of Stress Intergenerationally

Glossary

Childhood stressors

Adverse events or difficulties impacting on an individual in childhood; they typically involve specific experiences impinging on the child (e.g., parental loss; neglect, and physical, sexual, or psychological abuse), adverse family circumstances for the child (e.g., poverty, parental conflict, or parental psychiatric or criminal disorder), and child life events and difficulties. Childhood stressors can have an immediate impact or a longer-term impact in adult life.

Family environment

Experiences potentially common to the whole family unit. Thus, shared environment refers to experiences held in common, particularly within the household; nonshared environment refers to experiences that are different for various family members, specifically siblings, including the school and social arena.

Family studies

Studies that assess family members to look at the concordance of both experience and psychological disorders, as well as the intergenerational transmission of risk; they include parent to child comparisons, intrasibling and twin comparisons, and nontraditional family arrangements

Intergenerational transmission

Psychological disorder

Sibling relationships

Stress agency

such as step-parent households, lone parents, and adoptive parents and siblings.

The passing of the risk of disorder and adversity from parent to child and within families across generations; several mechanisms are likely to be involved, including social (perpetuation of high rates of adversity/stressors), psychological (poor parenting and negative interpersonal style), and biological (genetic or constitutional) factors.

A disorder that results from the negative impact of stressors on psychological health (i.e., being stressed), such as major depression and anxiety disorders; these disorders have been studied in relation to familial stress in both adults and young people.

Relationships between monozygotic (identical) twins, dizygotic (fraternal) twins, full siblings, half-siblings, and adoptive siblings. Studies of these relationships are central to behavioral genetic studies of families and include designs to show cascade effects when comparing similarities in characteristics and behavior in siblings and studies examining similarities and differences in siblings brought up together and apart. Likely genetic contributions can be inferred from the known genetic similarity of different types of sibling pairs and the similarity of their measured characteristics.

The quality of bringing about stressful situations through poor coping with adversity and mismanagement of interpersonal interactions. People with high agency in producing stress are more likely to have externalizing disorders, such as delinquency, antisocial personality disorder, substance abuse, and criminal behavior, which impact negatively on close others and family members. Assessing agency or independence of life events

	is key to establishing causal direction of the impact of stressors.
<i>Stress carriers</i>	Individuals who are both the recipients and bearers of high levels of stressors, which, although having no direct agency in their generation, can nevertheless transmit the stress to other family members. Mechanisms may be through passive and helpless coping styles, which perpetuate or increase difficulties. This is more common among those with the internalizing disorders such as depression and anxiety. For example, the choice of a partner with antisocial behavior may lead to a higher experience of stressful circumstances for both parents and children, even though specific difficulties are only indirectly brought about by the individual concerned.
<i>Stressors</i>	Adverse events or difficulties impacting on an individual.
<i>Vulnerability factors</i>	Characteristics that increase an individual's susceptibility to the impact of stressors; they interact with stressors to increase the risk of the onset of psychiatric disorder for particular individuals. Such factors can be psychological (e.g., low self-esteem and insecure attachment style), social (e.g., interpersonal conflict and lack of close confidants), or biological (e.g., irregular cortisol patterns). Vulnerability factors can be recent and ongoing or stem from early life experiences such as neglect or abuse in childhood.

Measurement of Stressors

The psychiatrist Adolf Meyer was the first modern practitioner in the 1950s to suggest that life events relate to psychopathology, developing a life chart system for recording the temporal relationships of life experiences and disorder. This method was developed further in the 1960s by Holmes and Rahe, with a questionnaire based on a summation of the quantity of environmental change in a given period in terms of a list of items representing both normative and non-normative changes such as moving one's residence or bereavement. The approach was then revolutionized in the 1970s both in psychiatry (by Paykel) and in social science (by Brown) by measuring the contextual threat or unpleasantness of events in more detail and by using more sophisticated assessment techniques to incorporate meaning into experience. This involved attending to the characteristics of events (such as whether they were undesirable or involved losses, entrances, or exits) by taking the context of the event into account when assessing its likely

unpleasantness, by examining the duration of the stressor (i.e., both chronic and acute), and finally by having the researcher assess the severity of the event according to benchmarked examples to circumvent the biases raised by self-report. Relevant context is crucial; for example, in the case of a pregnancy it is necessary to collect factual details of the experience including whether it was planned, the state of the marriage/partnership, the health of the individuals, and their financial and housing situation in order to assess its negative and potentially depressogenic characteristics. Although more attention was paid to life events because of their clear dating in relation to disorder, a role for chronic stressors or difficulties was also found. These involved problematic situations that continued over time and that frequently generated new events, for example, a financial difficulty involving debts that fluctuates in severity as new financial events occur. Severe events, matched to areas of ongoing marked difficulties, were found to be particularly pathogenic.

Studies in inner-London in the 1970s showed that severe life events (those that are highly threatening or unpleasant) were relatively common in the community with approximately one in three individuals experiencing at least one in a year. They were also found to be more common in working-class groups, in inner-city locations, and among single-parent families. Among events judged to be severe, three-quarters involved close relationships and these more often led to depression outcomes. The extension of this methodology to children was undertaken in the 1980s simultaneously by Goodyer and by Sandberg, following the Paykel and Brown traditions, respectively. A similar role for stressor and disorder was found in children but with chronic difficulties given a more prominent role. Parallel work looked at stressors simultaneously in parents and children and showed a large degree of familial patterning.

Stress and Disorder

Prior to the 1970s a relationship between the occurrence of life events and relapse of schizophrenia had been confirmed, and in the 1970s and 1980s the main development was the exploration in adults of the relationship of life events and the onset of affective disorder, particularly major depression. The relationship between severe life events and the onset of major depression was confirmed largely in samples of women and among mothers, in whom higher rates of depression are typically found.

A model was investigated prospectively, looking at the vulnerability characteristics of individuals who later succumbed to affective disorder when

encountering stressors. In prospective community studies, it was possible to identify interpersonal and cognitive factors that placed an individual at higher risk of affective disorder when later experiencing a severe life event. For adults, vulnerability factors encompassed family conflict (negative interaction with a partner or child), lack of a close confidant outside the home, and low self-esteem. When negative family interactions, low self-esteem, and severe life events all occurred, the risk for the onset of major depression was raised more than fourfold (47% versus 10% in the community at large). When lifetime experience was examined, the presence of neglect or abuse in childhood was highly related both to disorder and adult vulnerability, with one-third of women with adverse childhoods becoming depressed in a 12-month study period. A similar model is emerging for children, whereby family conflict and low self-esteem increase a child's susceptibility to disorder on encountering severe stressors. Stress can also have negative biological impacts, for example on stress hormones. Thus, abnormal cortisol patterns are associated with stressors and with a range of psychological and physical illnesses. Children experiencing chronic neglect and abuse have been shown to have abnormal diurnal cortisol patterns associated with behavior problems and poor functioning.

Lifespan models of disorder have examined linkages in early life adversity with later life impacts on disorder. In particular, neglect or abuse in childhood has been linked with adverse social trajectories, including unplanned home-leaving, teenage pregnancy, lone parenthood, high rates of adult life events and difficulties, and lower social class. The same early life experiences have been linked with negative psychological impacts at different life stages, including low self-esteem, helplessness, poor coping, and insecure attachment styles. These provide causal links between early-life family adversity and later-life stressors, which often impact subsequent family formation.

Shared Stressors and Disorders in Families

Studies have consistently shown that both stressors and disorder congregate within families and that these provide simultaneous, as well as later, life risks for both parents and children. Not only do family conflicts and severe events increase the risk of disorder in both, but there is also evidence that disorder in parents provides additional risk for children, and vice versa. Although most studies have shown links between mothers' and children's disorder, associations have also been shown with the fathers' psychological disorder. Disorder in both parents increases the risk for

the children substantially. Contributory risk factors from mothers include a history of affective disorder, current depressed symptoms, vulnerability characteristics, and ongoing chronic stressors, all of which play a part in the children's disorder. Although chronic stressors predict children's disorder independently of mental illness in the parents, the accompanying maternal impairment and poor parenting are associated with higher negative outcomes. This is likely because common stressors (e.g., marital conflict) affect the mothers and children and, in addition, mothers who are depressed are emotionally unavailable as a protective influence to help the children to cope. Thus, without the buffering effect of maternal support, the children are additionally susceptible to stress and can become symptomatic. The role of types of family stressors, family structure, sibling stressors, parenting, and parental disorder in familial patterning of stressors is now examined.

Types of Family Stressors

The types of family stressors that have proved to be important in predicting disorder in children involve family conflict and parental loss and bereavement. Children in families with parental affective disorder experience more acute stressful events, particularly those of an interpersonal nature, than children with parents with other problems, such as medical illnesses. However, chronic stressors are equally high in both. The mothers' disorder itself also acts as stressor for the children, thereby increasing risk. Children's responses to stressors is another contributor to risk, with negative self-concept being not only more common in children with higher numbers of stressors but also increasing the risk of disorder, particularly depression. These negative cognitions are associated with criticism and noninvolvement by the mothers. Although little work has been done on the agency of the stressors, aspects of both stress agency and stress carrying are likely to be present in the parents and children, consistent with the disorders and associated vulnerability.

Family Arrangements

Nontraditional family structures following the loss of a biological parent have been examined in relation both to stress and parenting and to its differential effects on siblings raised together and raised apart explored. Siblings brought up apart in different family arrangements show the greatest difference in adjustment, although even siblings raised together show different responses to family conflict and stressors. Studies agree that the loss of parents affects children differentially, even when objective aspects of the loss

are assessed. Poor parenting in terms of neglect and physical abuse are more common in certain family structures, such as when a biological and step-parent are present.

Sibling Stressors

Siblings' experiences have mainly been studied in the context of genetic studies to identify the sources of shared and nonshared environments to help explain the differences and similarities between siblings. These have used a variety of research strategies involving family studies, adoption studies, and twin studies to look at variations between siblings in personality, disorder, and experience of parenting. Interestingly, siblings have been shown to be largely different from one another in most assessments, and thus a large focus of such studies has been on assessing the role of the nonshared environment in explaining experience, personality, and psychopathology. The reasons for differences in siblings' environments include their relative ages, position in the family, gender, extra-familial experience such as school and social experience, and more random accidental or idiosyncratic experience. Although less work has been conducted on the degree to which stressors are shared by siblings, studies that do exist show a high degree of sharing of life events but less sharing of the negative impact of these events. Thus only approximately one-third of events held in common have a similar degree of negative impact for different family members. Twin studies have shown there to be a high degree of concordance for severe life events and a greater impact of such events in monozygotic than dizygotic twins.

In the late 1990s, an approach opposing the importance of family stressors emphasized the importance of children's experiences outside the family. Nonshared environmental influences in terms of school and social life were postulated as the critical environmental influences on child development and disorder, with familial influences being accounted for by genetic inheritance. Thus, sibling comparisons examining nonshared and usually nonfamily-based stressors, as well as positive experiences, have also been investigated.

Parenting

The quality of parenting has mainly been assessed around issues of the care and control of children. Poor parenting involves low levels of care and high control; at one extreme, this can involve the neglect and abuse of children. Parenting styles have also been categorized as authoritative, authoritarian, permissive, and disengaged, with the first of these being the most adaptive and related to positive child development. At the more extreme levels of poor parenting,

involving neglect and physical abuse, there is a high degree of shared experience among same-sex siblings. But where cold or critical parenting is involved, differential treatment by parents is much more common, with both favoritism and scapegoating of individual offspring occurring quite frequently. A process model of parenting shows the effects of the parents' own early development and personality, adult work history, marital relationship, and social network on parenting. This, in turn, impacts on child development and characteristics.

Parent Disorder

Psychiatric disorder in the parents can act as a magnet for familial stress, both in provoking the disorder and in perpetuating it. There is a strong relationship between concurrent disorder in parents (particularly mothers) and children. However, the chronicity and severity of the impairment by the disorder are more highly related to child's adjustment than to the actual parental diagnosis. Although the fathers' diagnoses exert weaker effects than mothers', the presence of disorder in both parents substantially increases the likelihood of disorder in the offspring. Because adults with depression have a higher likelihood of being partnered by people who have a psychiatric disorder, the likelihood of two parents being affected increases. Thus, 25% of husbands of women with depression have been shown to have disorders themselves, and as many as 41% of wives of men with a psychiatric diagnosis were similarly affected. This is argued to occur not only through assortative pairing, whereby individuals with a disorder appear to select partners with a similar impairment but also through the subsequent development of a disorder in the partner of an affected individual. This may be due to existing spousal difficulties or to the psychiatric disorder in both being caused by prior conditions in the family, such as poverty or conflict.

Transmission of Stress Intergenerationally

Because disorders and interpersonal difficulties run in families, three mechanisms of intergenerational transmission from parent to child have been investigated, with most studies suggesting that all three are likely to play a role.

Genetic Transmission

The genetic investigation of family influences on psychiatric disorder is engaged in the disentangling of genetic and environmental influences. A case has consistently been made for gene-environment correlations,

with children appearing to inherit some biological qualities that later result in depression and some environments that shape and pull their experiences in ways that lead to depression and other disorders. Three types of gene–environment correlations have been identified, and the current challenge in the field lies in assessing the role of each of these in the intergenerational transmission of both disorders and susceptibility to a disorder.

1. Passive genotype–environment correlations occur when children passively inherit an environment from parents that is correlated with their genetic predisposition.
2. Reactive genotype–environment correlations occur when children actively evoke environments associated with their genetic endowment.
3. Active genotype–environment correlations occur when the children actively seek out environments correlated with their genetic endowment.

Some progress is being made in seeking molecular genetic modes of transmission for adversity and disorder. For example, genetic deficiencies in monoamine oxidase A (MAOA) activity, responsible for metabolizing neurotransmitters such as norepinephrine (NE), serotonin (5-HT), and dopamine (DA), have been linked with aggression. The examination of violent offending using the Dunedin longitudinal study of children followed from birth showed a functional polymorphism in the gene encoding MAOA, which moderated the effects of childhood maltreatment on subsequent violent behavior in boys. An interaction between the level of maltreatment in childhood and low MAOA activity predicted a threefold higher conduct disorder rate and a tenfold higher violent convictions rate. This is an example of genetic factors playing a moderating or protective role. Thus, the low activity of MAOA and maltreatment accounted for only 12% of one male cohort studied but for 44% of the cohort's violent convictions. Eighty-five percent of cohort males who had the low-activity MAOA genotype and who were also maltreated developed some form of antisocial behavior.

Direct Impact of Parental Disorder

Another likely mechanism of transmission of stressor and susceptibility to disorder from parents to children is through the direct effect of the parents' disorder. In addition to providing additional stress for the children, the parents' disorder also presents the children with a poor role model for coping and reduces the possibility of any buffering effect from parental support. Three generations of influence have been identified, with women raised in dysfunctional families

likely to have impaired parenting skills from their parents (i.e., the grandparent generation), in turn increasing the risk of disorder in the children (i.e., the grandchild generation). However, evidence that individuals with disorders are more likely to be partnered with others with disorders means that this does not operate exclusively through the maternal line; disorder in both parents has been shown to provide the greatest risk for children.

The mother–child interaction is, however, particularly critical in intergenerational transmission, and this can trigger episodes either in the mothers or children, with evidence of influence in both directions. Depressed mothers have been shown to relate differentially to their children, with more negativity to dysfunctional children than to a normally functioning ones. In contrast, nondepressed mothers are less likely to acknowledge dysfunctionality in their children and therefore treat them more similarly. Thus, characteristics of both the parents and the children play a part.

Correlates of Parental Disorder

For children, as for their parents, psychiatric disorder is a consequence of adversity, but it also leads to the perpetuation of adversity. The most common family adversity associated with disorder is interpersonal, involving both marital conflict and conflict with children, although poverty and social isolation are also implicated. Susceptible individuals are thus capable of either being the agents of stress for close others or being the recipients and carriers of such stress and passing it on to others. Where both parents in a family have disorder, the accumulation of stressors for all family members is likely to be great. Thus negative family interaction can be a function both of parents' vulnerability characteristics (e.g., poor interpersonal relating, poor support, and low self-esteem) and of symptoms of psychological disorder (e.g., depression, anxiety, and antisocial behavior). Thus, intergenerational studies with mothers and young adult offspring interviewed independently show an important role for neglect/abuse in the offspring in disorder but with separate causal linkages from maternal depression and maternal vulnerability. It is of note that the perpetrators of physical abuse in children are rather more likely to be the fathers or surrogate fathers, despite the intergenerational impact observed for mothers. Thus, the mothers' role can be both a carrier and agent in stress, with both being conveyed to the offspring.

The reasons for familial stress patterning are therefore varied. The congregation of stressors within family groupings is due to both common and individual

influences. Negative interpersonal functioning, poor parenting, poor coping, and family disadvantage are key factors. Biological factors involving the genetic transmission of risk and the physical impacts of stress are increasingly being discovered as contributing to final explanatory models.

Stress and the Family

Theoretical Models of Family Therapy

What Family Therapy Can Achieve

Indications for Family Therapy

Glossary

Differentiation of self The degree of emotional separation between a person and his or her family of origin. More differentiated individuals have a better awareness of the influence of their emotions, behavior, and actions and are less dependent on approval of others for their decisions.

Double bind

Communication characteristics of a system that produces conflicting definitions of incongruous messages between members of a family, leading to stress and anxiety.

Enmeshment/disengagement

Enmeshment is a type of family relationship in which the family members are fused and are unable to define their roles and boundaries. Subsystems are not well defined, and the hierarchy of executive functions is unclear. Disengagement refers to a lack of relatedness and binding between family members, who appear uninvolved and distant.

Homeostasis

Steady state of any living system that is regulated and maintained as it faces the external environment. If the system faces stress and breaks down, it attempts to repair itself so that a state of constancy and balance is maintained.

Identified patient

The person who bears the symptoms and is the reason for the family to seek treatment. However, from the family system

	point of view, individual psychopathology is maintained and or amplified by the family, if not a consequence of family pathology.
<i>Pseudo-mutuality</i>	A facade of harmony and pretending to share same behavior, feelings, and attitude in a family at the expense of lack of individuation in its members. Anything that threatens to deviate from the sameness of the structure and roles provokes a great deal of anxiety.
<i>Rubber fence</i>	A specific state of relationship between the family system, its members, and the social environment. It protects the family from any intrusion or departure from its norm and incorporates items that fit and rejects those that appear noncomplimentary.
<i>Scapegoat</i>	A person who is recruited by the family system to become the problem, instead of the family system attempting to resolve its conflicts.
<i>Schism and skew</i>	Schism is a pattern of marital relationship in which the members of a couple fail to reach an agreement on role reciprocity and therefore undercut or coerce each other. Skew in a marital relationship means that one member of the couple has significant pathology, but the other goes along with it, and all conflicts, while present, are hidden.
<i>Triangle</i>	When conflict or anxiety rises in a dyadic or a two-person relationship and a third person is included to diffuse the conflict. The pathological form of triangle is a rigid triangle wherein conflicts are never resolved in the dyad, and the third person is put in a position of either conflict of loyalty or alliance with one member against the other.

Stress and the Family

In a living system, nothing is static. Different psychological, biological, and social forces are continuously impinging on the system to synchronize and change. Stress on the family system disturbs its homeostatic equilibrium. In response, the system must mobilize its internal and external resources, become flexible enough to produce alternative modes of adaptation, be able to exchange roles and functions across its subsystems, reorganize to meet the demands of the stress, and redefine itself after adjustment to the stress.

The family system must be assessed as a whole, with a set of functions, relationships, and roles, which are continuously changing as the social structure

surrounding the family system is changing. Therefore, in evaluating the effects of stress on the family system, one must be aware of the cultural, social, and historical makeup of the family, as it influences the experience of, meaning of, and response to stress.

The types of stress on the family are mainly the following:

1. The stress of transitions in the family's developmental stages (becoming a couple, birth of first child, children transitioning into adolescence, first child leaving home, last child leaving home, retirement and empty nest, sudden illness and death of a family member, chronic illness in a family member, threat of dissolution of the family such as separation and divorce, remarriage and blended family, illness or death of grandparents, etc.)
2. Outer stressors, such as loss of job, a move to a new location, changing schools, economic loss, catastrophic events such as flood and earthquake, and crime.

Regardless of the type of stress, the family system must first recognize the stress, then attempt to adjust and reorganize in order to cope with it. Adjustment and reorganization include changes in the structure, function, and roles of the system, which will be new and unfamiliar to the members and may bring anxiety and uncertainty with them.

If the family characteristics and functioning were problematic and conflictual to begin with, including poor communication skills, unclear boundary definition, poor parental skills, and marital conflicts, then the family structure may skew further in the face of stress and will have difficulty in reorganizing and readjusting. This may result in either poor adaptation or development of symptoms in vulnerable members (biologically or constitutionally), such as substance abuse, depression, suicide attempt, school or behavioral problems, eating disorder, infidelity, and threats of separation or divorce.

These families may mobilize pathological coping mechanisms, such as denial, blame, scapegoating, detouring of conflicts, and developing rigid triangulations, which may result in an increase of perceived stress in its members. Although denial can serve as a protective defense mechanism at first, if it persists it will impede the family's coping, because the family will resist change and continue to limp along as if no modifications were required. However, their established patterns will not be sufficient, and the stress may plunge the family into a state of crisis. The functioning of the family system will halt, and the system will be incapacitated, in a state of disequilibrium, and unable to function.

Lack of flexibility in gender roles and division of labor can cause rigidity and restrictions in the system, which will reduce resources necessary for coping. Families that are isolated from their social network and community also have restricted coping resources. The family system can recover from the state of crisis with the help of family therapy.

Family members can grow from the experience of stress and learn how to manage future stresses. Family therapy can help them to identify the stress, become more cohesive, communicate better among themselves and with the outer environment, recruit social and community resources, respect interpersonal boundaries, and avoid blame.

Theoretical Models of Family Therapy

Overview

Family therapy is a type of psychotherapy in which the unit of treatment is the family (whether nuclear or extended), and not the individual. It assumes that problems and symptoms emanate from unhealthy interactions in the family system and not solely from the psychological or subconscious problems of the individual. The theory uses circular rather than linear thinking; each individual is part of the larger group, with continuous interaction and feedback processes between the two.

In general, family therapy is based on family system theory. It examines family interactions, interpersonal relationships, and communications and aims to change unhealthy patterns. This theoretical model was introduced in late 1940s and early 1950s, emanating from the study of schizophrenic patients and the link between exaggerations of their symptoms and their family interactions. Family system theory assumes that the family system is in a constant state of change and balance, and it attempts to achieve homeostasis and adaptation to change by mobilizing alternative interactions. When the system can not adapt successfully due to stress, rigidity of patterns, and/or psychological features, problems and symptoms ensue in different members. Consequently, adaptation is inappropriate, and a state of dysfunctional homeostasis settles in.

The early family therapists hypothesized that whenever the family system's homeostasis is threatened, symptomatic behavior in one member may become a way to preserve the family's equilibrium. Therefore, the concepts of scapegoating and the identified patient were introduced.

Early family therapists also hypothesized that many of the preceding phenomena occur through a feedback process and nonverbal communications, through

sequence of interactions. At first they attempted to examine the communication of schizophrenic patients and their families, and concluded that there are series of contradictory messages transmitted to the patient. The concept of double bind was introduced, which was considered the essential ingredient in the child-parent interaction, specifically the mother (the concept of the schizophrenogenic mother), in which a family member receives two contradictory messages that he or she can not obey or disobey. Later the concept of double bind was extended from a two-person system to a three-person system, as attention was drawn to fathers as well as mothers. Interactions in the marital relationship were found to be dysfunctional and pathological, and the concepts of schism and skew were introduced. They highlighted patterns of hostility, undercutting, domination, passivity, and distortion.

Other family therapists studied communication patterns and family roles in schizophrenia and identified pseudomutuality as a feature of families with a schizophrenic member. These families appear cohesive on the surface but are in deep conflict underneath. They may also erect a boundary around the family that will extrude any input that will not fit their norm (a rubber fence) and will only allow input that will fit their norm.

These theories were later applied to other family systems with a member identified as carrying a psychiatric diagnosis, such as an eating disorder, depression, or substance abuse. Although all family therapists agree on the basic principle of how a dysfunctional family can lead to stressing a vulnerable member(s) so that symptoms develop and are maintained and amplified, the techniques that have been developed to treat families are quite different from each other. However, each strives to establish a less stressful state in the family.

The length of a course of family therapy is usually shorter than individual therapy, ranging from several sessions to several months. On the whole, the therapist attempts to change the dysfunctional structure and functioning of the system, rather than address changes in the individual member. When therapists attend to symptoms, they are treated as part of a complex system of interaction and feedback processes in which symptoms have become faulty resolutions for other family problems. The therapist strives for a change in rigid behavioral patterns, increased communication, healthier interactions, and improved problem solving among all members.

Examples of Theoretical Models

Major theoretical orientations of family therapy include psychoanalytic (Ackerman), systems (Bowen), structural (Minuchin), strategic (Haley, Madanes),

experiential (Whitaker), communicational (Satir, Bateson, Watzlawick), object relations (Framo, Nagy), and a few others, such as constructivist and Milan's system of counter paradoxical family therapy.

Psychoanalytic family therapy Ackerman theorized that a healthy family is in a state of constant homeostatic balance, which is dynamic and changing as the family grows in its developmental stages and as new stresses occur to which the family needs to adapt. The dysfunctional family cannot adapt to the required changes, and therefore the various family functions become faulty and lead to problems and symptoms in its members and possibly to disintegration of the family. Therefore, change can occur through implementing improved problem solving, learning healthier communication, and diminishing the scapegoating of its members.

Family Systems Therapy

Bowen developed family systems therapy, theorizing that the basis of human relationships is not a two-person system but a three-person one. He stated that when conflicts and anxiety develop in a relationship, invariably a third person becomes involved who will side with one of the other two. In this threesome, two individuals are close, and the third one is on the outside. This is the basis for the concept of triangles in the family. The triangle may appear to diffuse the anxiety, but conflicts remain unresolved.

Triangles are constantly shifting and unstable and have a tendency to interlock with other triangular relationships. Individuals learn from their family of origin how to operate in triangles. When the adaptive level of functioning in a family is pathological, the individuals in that family are more likely to resolve anxiety with triangulation and are less differentiated. The concept of triangles and triangulating was later applied to larger systems such as organizations and small groups.

Bowen stated that each family is part of an undifferentiated ego mass, and each member strives to differentiate from it, to develop one's own sense of self, and to detriangulate oneself. He also stated that patterns of relationships and handling stress are a part of a process that is transmitted across generations. When getting caught in triangulated relationships with their family becomes too intense and stressful, members may try to distance themselves emotionally or physically, or they may try to cut themselves off from the family. However, similar patterns will be recreated and repeated in other relationships that the individual develops.

This model also introduced the concept of family projection process, which means that the

emotional processes are transmitted, for example, to a child, who as a result may develop difficulties in differentiation of self.

The family system theory of Bowen states that historical patterns are factors in symptom production as well as change; therefore, the main tool of treatment is using a genogram or diagram of the family's three generations in detail, demonstrating sets of relationships, conflict areas, and triangular relationships, and then exploring methods of unlocking and changing them. Bowen encouraged families to resolve issues with their families of origin and attempt to achieve separation and differentiation from them.

The goal of treatment is understanding the three-generation system of involvement in the symptoms. The main therapeutic technique is helping and teaching the family to differentiate and detriangulate themselves from their family of origin ego mass, which will lead to healthier relationships on the whole.

Structural family therapy Structural family therapy (Minuchin) presents a clear model of what is considered a normal family system. This is a system with a clear hierarchy of power, clear boundaries between members and the family subsystems (subsystem of parents and children), no cross-generational coalition, and clear cross-generational boundaries.

Minuchin presented a model of pathological family enmeshment in which boundaries are blurred, the hierarchy of power is unclear, cross-generational alliances and coalitions are present, and executive functions of the family are hampered. He stated that a dysfunctional family cannot adapt to developmental and extrafamilial stresses and it therefore recruits a vulnerable member who becomes symptomatic.

Minuchin applied his methods to severe problems of childhood and later to eating disorders. Structural family therapy's major contribution to the field was in the treatment of psychosomatic illnesses such as asthma and illnesses in which an emotional component was detrimental to control and compliance, such as diabetes. Research with diabetic and asthmatic patients done by structural family therapists clearly showed that family stress levels correlated with induction of an asthmatic attack or a rise in blood glucose level of the patient, and when the stress subsided, the asthma subsided and the blood glucose level returned to normal. Conflicts in the family correlated with exacerbation of medical symptoms, which was supported by laboratory data. Minuchin demonstrated that family therapy and reducing the family's conflicts and stress can indeed reduce the number of emergency visits for both the asthmatic and the diabetic family member.

Structural family therapy was also applied to patients with eating disorders, ranging from bulimia to anorexia, and to patterns of lack of conflict resolution and rigidity that were dysfunctional and therefore maintained and amplified the preceding symptoms. Once these patterns were addressed and changed, the eating disorder improved. Techniques used in this theoretical framework include joining, establishing clear subsystems, expanding the alternative ways of problem solving, strengthening the boundaries between generations, relabeling symptoms, creating intensity leading to change, increasing flexibility, modifying dysfunctional interactions, clarifying the hierarchy of power, and restructuring.

Strategic family therapy Strategic family therapy and the problem-oriented approach (Haley) also adhere to a systemic model of family interaction, stating that symptoms maintain homeostasis. Strategic family therapy studies the sequence of interactions among family members that leads to symptoms and then attempts to change this sequence to a better-functioning one and a healthier hierarchy. The symptom is also a solution, although an unsatisfactory one. It is both supported and opposed by other members' behavior. Therefore, the therapist has to identify the sequence of interactions that both reinforces and exacerbates it.

In this model, a historical perspective of the family is not studied, nor is the larger context or where the meaning of the symptom is embedded. The focus is on the presenting problem or symptom and not on the family. However, in order for the problem to improve, the organizational sequence that maintains the problem must change. Change is accomplished by prescribing strategies, positive reframing, changing dyadic relationships that are involved with the symptom, reversal of roles, and use of paradoxical assignments and interventions. Symptoms are changed through changes in hierarchy, coalitions, and communication. This model clearly adheres to a briefer period of therapy.

Experiential family therapy The experiential model (Whitaker) focuses on process and growth in therapy. The family is challenged by being offered a variety of alternative ways of interacting, including absurd ones, as a method to unstick the family. Change is induced by creating new experiences, personal growth, and marking boundaries between generations. Individual and family creativity and growth are promoted. The problems or symptoms are viewed as systems problems. In this model, an attempt is made to join the system in the beginning, but later in treatment the therapist distances and becomes an outside

consultant to the system, encouraging the family to take the initiative in making changes.

Counter paradoxical family therapy The counter paradox model of the Milan group suggests that in a dysfunctional family, the members' response to each other is often paradoxical and illogical. This model attempts to counter the paradox by the use of a team of therapists, circular questioning (to gather more information), positive connotations, remaining neutral, increasing the time interval between the sessions, prescribing family rituals, and systemic prescriptions.

What Family Therapy Can Achieve

Family therapy can achieve the following:

- Help the family to understand the patterns of their interactions and relationships as a whole, instead of focusing on one member as the scapegoat.
- Identify conflicts and defects within the family structure and help members to develop new methods of resolving problems.
- Identify internal and external resources and strengths.
- Provide support, education, and guidance in handling inner and outer stresses.

The main rule of thumb in conducting family therapy is that all members who are identified as key members must participate; otherwise, it will not be effective.

Indications for Family Therapy

Indications that family therapy is needed include the following:

- Substance abuse in one or more family member
- Chronic psychosomatic disorder or other chronic medical illness in one member
- Physical or emotional abuse in the family
- Marital conflict
- Poor parental skills
- Eating disorder in one member
- Diagnosis of major psychiatric disorder in one member such as schizophrenia or bipolar disorder
- Depression in the family
- Any behavioral problems or psychological symptoms in a child or adolescent
- A dysfunctional adult offspring in the family
- A traumatic event experienced by the family

Psychiatric Approach

Organizational and Occupational Health Approach

Psychophysiological Approach

Psychosomatic Approach

Conclusion

Glossary

Burnout

A state characterized by emotional exhaustion that may occur after exposure to prolonged stress.

Hypothalamic-pituitary-adrenal (HPA) axis

Part of the neurohormonal stress system. Both increased and decreased activity of the HPA axis can be observed, depending on the nature of the disorder.

Neurasthenia

A state characterized by fatigue, impaired cognitive functioning, and increased emotional sensitivity.

Vital exhaustion

A state characterized by unusual fatigue and loss of energy, increased irritability, and feelings of demoralization; often precedes cardiac events. In the original conceptualization of the exhaustion construct, the term vital was included to reflect the far-reaching consequences of this condition on daily life function (similar to vital depression).

Fatigue is a common symptom that can substantially interfere with daily functioning and quality of life. A large literature indicates that episodes of extreme fatigue are precipitated and maintained by emotional distress. A substantial number of individuals (5–20% of the general population) suffer from persistent fatigue that interferes with routine daily life activities, and fatigue is one of the most common presenting complaints in primary care. Prevalence estimates of fatigue depend on the measurement instruments, cut-off points for presence versus absence, and the persistence of the complaint. Patients generally regard

fatigue as important because it is disabling, whereas physicians often do not place a strong emphasis on fatigue because it is diagnostically nonspecific for most if not all diseases.

Several theories have been developed to conceptualize and investigate fatigue. These theories describe fatigue as a pollution of the *milieu interieur*, as an energy problem, as a breakdown in nervous system functioning, or as an evaluative motivational assessment of an individual's psychophysiological condition in relation to exogenous demands, resulting in a decision to either continue or discontinue an activity. These theories have strengths and limitations, and reflect the way in which scientists organize and operationalize their approaches to investigating a coherent set of symptoms. There are overlaps and distinctions between the approaches to the origins and treatment of fatigue, depending on the investigator's fields of interest and scientific background. In the following sections we provide a selective review of these approaches.

Psychiatric Approach

Since the late 1800s, much debate has arisen addressing the question of whether fatigue states should be distinguished from depressive mood disorders. There is little doubt that depressed individuals often feel tired and that fatigue is one of the diagnostic symptoms for depression. However, not all individuals who feel depleted of energy suffer from mood disturbances, lack of self-esteem, or guilt feelings. Therefore, psychiatric constructs have been developed to describe a condition that is mainly characterized by profound fatigability. In 1869, George M. Beard introduced the concept neurasthenia to describe an organically based disorder characterized by fatigability of the body and mind, largely resulting from environmental factors. Neurasthenia was primarily treated by rest and reportedly common among well-educated and professional individuals. Other concepts that have been developed to describe fatigue states include effort syndrome, neurocirculatory asthenia, or postinfectious fatigue syndrome.

More recently, the chronic fatigue syndrome (CFS), myalgic encephalomyelitis (ME), and also posttraumatic stress disorder (PTSD) have been introduced as conditions in which fatigue and distress play a primary role. CFS is an operationally defined syndrome characterized by a minimum of 6 months of severe physical and mental fatigue and fatigability made worse by minor exertion. Because of the similarities among the prior neurasthenia construct, CFS, and ME, it has been questioned whether these more recent

concepts are mainly "old wine in new bottles." PTSD describes the sequels of exposure to severe psychological distress, such as occur during major disasters, war, and other life-threatening events. Increased fatigue and fatigability belong to the major characteristics of PTSD. Detailed research has revealed that some symptoms are relatively specific for PTSD and CFS, justifying their heuristic value. There is, nonetheless, substantial overlap among the symptoms that constitute these postulated syndromes, which may suggest that stress is a common factor.

Psychiatric classifications and diagnoses were originally based on the presumed pathophysiological origins of a complaint. In contrast, contemporary diagnostic classifications, such as the *Diagnostic and Statistical Manual of Mental Disorders* (4th edn.; DSM-IV), are predominantly based on the description and classification of symptomatology. DSM-IV includes PTSD, but does not include any of the other fatigue-related constructs or syndromes. DSM-IV lists decreased energy, tiredness, and fatigue among the symptoms of depressive mood disorders or dysthymia. Thus, the most commonly used classification system for mental disorders does not make a distinction between depression and other fatigue states.

Organizational and Occupational Health Approach

In occupational medicine and occupational psychology, fatigue is mainly approached as the result of an imbalance between demand and supply or as a breakdown in adaptation to stress. During the last decades, much attention has been given to burnout as the end point of long-lasting work-related stress. Burnout is a negative state of physical, emotional, and mental exhaustion that is the result of a gradual process of disillusionment. The concept of burnout was first used by Freudenberger in the mid-1970s to describe a common psychological characteristic observed in health-care professionals. Freudenberger observed that many of the volunteers with whom he was working experienced a gradual emotional depletion and a loss of motivation and commitment. Burnout has three main components: emotional exhaustion, depersonalization, and reduced personal accomplishment.

There has been substantial debate about the optimal definition of the burnout construct. However, this debate has not prevented fruitful empirical research, including Maslach's successful development of a reliable scale to measure burnout. This scale assesses the three dimensions of burnout (emotional exhaustion, depersonalization, and reduced personal accomplishment) and has become the gold standard

for the assessment of burnout. Empirical research has shown that the emotional exhaustion component is related to depression, whereas the relationships between depersonalization and personal accomplishment with depression are less strong.

The burnout literature is more concerned with situational antecedents than with individual differences as the determinants of burnout, probably because of the occupational health origins of this construct. The extension of the burnout concept to nonoccupational domains (e.g., feelings of emotional exhaustion caused by marital conflicts) has been controversial, especially because the concepts of depersonalization and reduced personal accomplishment are less applicable outside the realm of occupational settings. Therefore, the contributions of research on burnout to fatigue lie primarily in the identification of social and occupational determinants.

Psychophysiological Approach

Psychophysiological approaches address behaviors, emotions, and cognitions that correspond with physiological reactions to normal and abnormal, internal or external stimuli. For example, psychophysiologicals and other behavioral scientists investigate the influence of fatigue on inflammation, as well as how the mental state is influenced by inflammation. The stress system receives much attention in these types of psychophysiological research designs.

The autonomic nervous system and neurohormonal processes play a crucial role in the human stress response. The autonomic nervous system involves two branches: the sympathetic nervous system (involved in the acute stress response) and the parasympathetic nervous system (which is commonly more active in periods of rest and, in general, counterbalances the sympathetic nervous system). The neurohormonal stress response is complex and involves the sympathetic-adrenomedullary (SAM) system and the HPA system. The stimulation of the SAM system is characterized by increased secretion of the catecholamines epinephrine and norepinephrine, as well as increased heart rate and blood pressure, sweating, palpitations and other vegetative symptoms (i.e., related to autonomic nervous system activation). Most of the autonomic nervous system and neurohormonal responses in response to stress exposure are normal, enabling the organism to adapt to environmental changes.

The HPA axis response displays important divergent concomitants of increased versus decreased activity. Increased HPA axis activity is observed in response to acute stress; increased HPA axis activity characterized by increased secretion of cortisol is also well documented among individuals with

melancholic depression, panic disorder, central obesity, and Cushing's syndrome. These elevated cortisol levels may coincide with the suppression of inflammation. In contrast, decreased HPA axis activity has been observed in chronic stress, persistent fatigue, atypical depression (i.e., hyperphagia and hypersomnia), and nicotine withdrawal. These conditions are associated with a decreased production of cortisol and purportedly with the activation of immune-mediated inflammation.

During inflammation, the body produces cytokines, which play a pivotal signaling role in immune system activation. Some of these cytokines reach the brain or elicit the release of cytokines in the brain, resulting in what has been labeled sickness behavior, characterized by locomotor retardation, general malaise, anorexia, and inhibition of sexual behavior. Sickness behavior is part of the defensive response to infection or inflammation. Evidence consistently demonstrates that fatigue and inflammation are interrelated. Thus, there is probably a bidirectional or circular association between inflammation and fatigue, which is mediated in part by the central and autonomic nervous systems. The psychophysiological approach makes a unique contribution to the study of fatigue by investigating which symptomatic and physiological reactions belong to normal health-protecting behaviors and which reactions are markers of a breakdown in adaptation to environmental challenges.

Psychosomatic Approach

In psychosomatic medicine, fatigue is approached in several ways, depending on the nature of the coinciding medical disorder. For example, among patients with cancer, fatigue is considered as a (still poorly understood) consequence of the disease and its treatment. Programs are mainly directed at coping with the fatigue. In patients with multiple sclerosis, fatigue is particularly disabling symptom, distinct from depressed mood or physical weakness.

In coronary artery disease, fatigue and exhaustion are of particular interest because it is well established that exhaustion (i.e., feelings of unusual fatigue, loss of energy, and increased irritability and demoralization) is an important precursor of myocardial infarction and sudden cardiac death. Exhaustion and depression also predict recurrent cardiac events among high-risk populations, and more research is needed to further document the divergent validity of these two partially overlapping constructs.

Based on the predictive value of exhaustion and depression for future adverse cardiovascular outcomes, two different intervention approaches have

been investigated recently. Many scientists interpret the premonitory symptoms of extreme fatigue as manifestations of a clinical or subsyndromal depression; consequently, Beck's cognitive therapy has been used to treat coronary disease patients with depressive symptomatology. Other investigators have approached the same symptoms as manifestations of a sustained state of exhaustion resulting from long-term exposure to uncontrollable emotional distress. This perspective emphasizes the similarity between exhaustion and the psychological consequences of decreased HPA activity following chronic stress. Interventions targeting exhaustion use group therapy, including relaxation and reducing stressors that can lead to exhaustion. The effects of both types of interventions on the risk of new coronary events have been tested in well-designed, randomized, controlled intervention trials. Neither of the two strategies succeeded in demonstrating that a reduction of depression or exhaustion reduced the risk of a new coronary event. However, the interventions were successful in subsamples (determined *a posteriori*). It is reasonable to assume that future trials will profit from the lessons learned in these pivotal studies. Such trials may demonstrate that a behavioral treatment of fatigue and depressive symptomatology will not only improve quality of life but also reduce the risk of recurrent cardiac events.

Conclusion

Fatigue is a ubiquitous phenomenon. Less than 10% of patients presenting with fatigue in primary care present with a disease that plays a direct causal role in this symptom. The law of parsimony has accompanied fatigue research and will accompany future work. It has been debated whether concepts such as neurasthenia, burnout, and vital exhaustion are needed and whether the procrustean bed of DSM-IV does more harm than good in stress research. Each of the aforementioned approaches has contributed to our obtaining more insight into the origins of fatigue, its biological and physiological correlates, and the possibilities and limitations of helping individuals who suffer from unusual fatigue. The domain of fatigue research has unique epistemological problems, which require further scientific attention. More research is needed on the distinction between fatigue as a health-protecting factor and fatigue as a marker of overtaxing of the body. The precipitating and maintaining factors of chronic fatigue conditions are complicated because some of the original etiological factors may have become undetectable (e.g., the long-term consequences of viral infections). It will be difficult to answer the question of whether chronic fatigue can be

best approached as a form of psychological adaptation to prolonged and uncontrollable environmental challenges or whether fatigue is a manifestation of depression and/or a dysfunctional neurohormonal system. Future multidisciplinary research will continue to add to our understanding of the role of stress and other psychological factors in the origins, mental and somatic consequences, and treatment of fatigue, particularly in conditions in which fatigue is a known predictor of adverse medical prognosis.

Components of Fear

Measures of Fear

Fear Stimuli

Fear Learning

Pathological Fear: Phobias

The Neurophysiology of Fear

Glossary

<i>Agoraphobia</i>	An intense fear and avoidance of situations in which one would be helplessly exposed in case of a panic attack.
<i>Amygdala</i>	A collection of interconnected nuclei in the anterior medial temporal lobe, which is the hub of the brain network controlling the activation of fear responses.
<i>Autonomic nervous system</i>	A part of the peripheral nervous system concerned with the metabolic housekeeping of organisms. In general, the activation of its sympathetic branch results in the expenditure of energy and the activation of the parasympathetic branch results in the restoration of energy.
<i>Fear</i>	The emotional state associated with attempts to cope with threatening events.
<i>Social phobia</i>	An intense fear and avoidance of being socially evaluated or scrutinized.
<i>Specific phobia</i>	An intense fear and avoidance of specific objects or situations.

Fear is an activated, aversive emotional state that serves to motivate attempts to cope with events that provide threats to the survival or well-being of

organisms. The coping attempts are typically centered on defensive behaviors such as immobility (freezing), escape, and attack.

Components of Fear

A fear response comprises several partially independent components, such as subjective feelings (accessible through verbal reports), peripheral physiological responses, and overt behavior. In humans, the phenomenological quality of fear is best described as an aversive urge to get out of the situation. This is a familiar feeling for every human being and a frequent target for artistic representation.

Fear is closely associated with the activation of the autonomic nervous system. Depending on situational constraints, the direction of this activation may differ. If the threat is not imminent and appears stationary, the typical response is one of freezing or immobility. This is associated with enhanced attentiveness toward the environment and the potential threat stimulus and with a vagally mediated deceleration of the heart. If the threat is imminent or approaching, there is a pervasive mobilization of the sympathetic branch of the autonomic nervous system, including heart rate acceleration and increases in blood pressure and circulating catecholamines (primarily epinephrine) from the adrenal medulla. These responses lay a metabolic foundation for taxing overt reactions of flight or fight.

In terms of behavior, there is an important distinction between expressive and instrumental overt acts. Expressive behavior includes automatic tendencies to withdraw from the threat and a typical facial expression of fear. The latter is composed of elevated eyebrows, wide open eyes, and a mouth that is either slightly opened or shut with depressed mouth corners. Instrumental behavior primarily concerns escape from and avoidance of the fear stimulus.

Measures of Fear

Measures of fear can be readily derived from the various components of fear. The intensity of the subjective component of fear can be directly assessed through ratings that may be anchored, for example, at a zero level of no fear at all, with a maximal level of fear corresponding to the most intense fear ever experienced by the subject.

Many fear indices have been derived from effectors innervated by the autonomic nervous system. Some of these measures, such as heart rate deceleration and skin conductance responses, are primarily related to the increased attentiveness associated with the initial stages of fear. Other measures, such as increases in heart rate or blood pressure, reflect the sympathetic mobilization that supports active coping attempts. Endocrine indices are available from the adrenal medulla and the adrenal cortical hormones. Measures among the former, such as circulating epinephrine, are often assumed to index successful coping, whereas measures from the latter, such as cortisol, are regarded as related to failing coping attempts.

Many behavioral measures have been used to assess fear. Typically they focus on avoidance behavior. For example, in a standard behavioral avoidance test to assess specific human fears, subjects are encouraged to approach their feared object as close as they dare, and the minimal achieved distance (touching included) is taken as inversely related to avoidance. In animals, the strength of escape behavior or the duration of freezing responses can be measured, depending on the experimental situation. In rodents, who typically freeze when fearful, the effect of a fear stimulus can be assessed by its interfering effect on a regular background behavior, such as operant lever pressing for food rewards on a variable interval schedule.

On the premise that defensive reflexes are primed by an induced fear state, the modulation of such reflexes by fear stimuli can provide accurate information about fear both in animals and humans. Typically, the startle reflex is studied using whole-body startle in rodents and the eyeblink component of startle in humans. The typical result is an enhancement of the startle reflex to a standard startle probe stimulus (e.g., a white noise with abrupt onset) when it is presented against a background of a fear stimulus compared to when the probe is presented alone.

It is important to realize that different measures of fear are not necessarily highly intercorrelated, even when assessing the effects of a common fear stimulus. This is because the fear response is better conceptualized as a loosely coupled ensemble of partially independent response components, sensitive to various

modulating parameters, than as a unitary internal state mechanically elicited by the appropriate fear stimulus.

Fear Stimuli

There are innumerable events and situations that are feared by humans. Loosely speaking, they have in common that they provide a threat to the integrity of the individual, either in a physical or in a psychological sense. Many of the stimuli that are feared by humans are feared by other mammals as well. They include, for instance, loud noises, predators, and dominating conspecifics.

Classification of Fear Stimuli

In general, behaviors can be classified as communicative or noncommunicative depending on whether they elicit an active response from the environment. Communicative behavior is directed toward other living creatures, whereas noncommunicative behavior is directed toward the physical environment. Communicative behavior can be further subdivided into behavior directed toward members of another species, such as in predator-prey relationships, and members of the own species in what is commonly regarded as social behavior. Applied to fear, this classification system distinguishes among fear of physical stimuli, fear of animals, and social fears.

Physical stimuli Humans and other animals fear many types of physical stimuli, particularly those that may inflict tissue damage, thus inducing pain. A primary stimulus dimension is that of intensity. Highly intense stimuli of any modality may induce pain, and certainly they elicit fear and associated attempts to escape in most animals. Complex events that incorporate high-intensity stimulation, such as lightning and thunder, often evoke intense fright. But there are other complex events or situations whose fear-eliciting power is less directly dependent on simple stimulus dimensions. The effectiveness of such situations can be understood only in relation to the recurrent threat they have provided throughout evolution. Examples that come to mind include heights, small enclosures, wide-open spaces, and darkness or light (for species primarily active in daylight or at night, respectively).

Animal stimuli Species typically share ecological niches, and thus the presence of other animals has been a shaping force in evolution. Species compete for similar food supplies, and in predation, one species

provides the food supply for another. In this latter case, avoiding capture as prey is a prerequisite for reproduction; therefore, potential prey species fear their predators. There is also a widespread fear of potentially poisonous animals, such as snakes, spiders, and insects, and these fears may be better represented as fear of (and disgust for) contamination rather than as fear of the animal itself.

Social stimuli No animal is more dangerous to humans than other humans; the most dangerous predators are humans who are ready to use violence to exploit the resources of other humans. Conflicts with fellow humans, however, are not restricted to fights about tangible resources. Typically they deal with something more abstract, but also more pervasive – power. Like other primates, human groups are structured in terms of dominance, that is, some members dominate others. Fear is part of the submissiveness shown by the dominated group members when confronting a dominant conspecific. This fear is not automatically connected to escape or (least of all) to attack, but it is shown in a readiness to emit signals of submissiveness and in refraining from competition. In humans (and other primates), it denotes a fear of being negatively evaluated, of losing face in front of the group, rather than of physical harm.

Moderating Factors

Several general dimensions modify the fear elicited by these types of fear stimuli. One of them is closeness. In general, the closer the fear stimulus, the stronger the fear response. This may, in fact, provide an explanation for the effect of stimulus intensity on fear – an intense stimulus is likely to be very close. Prey animals (e.g., gazelles) show a minimal reactive distance before they overtly take notice of a predator (e.g., a lion). If the predator is far away or appears to be resting, it is monitored only by increased attention. If it gets closer or appears to be hunting, the attention enhancement is accompanied by defenses such as immobility. When the predator gets dangerously close, finally, there is active defense such as flight.

A second moderating factor is movement of the stimulus and the direction of the movement. Approaching objects, in general, elicit more fear than stationary objects or objects moving away. For example, more fear is generated by a fearsome authority figure who is heading in our direction than by one who is heading in another direction.

A third class of moderating factors involves predictability and/or controllability of the fear stimulus. An abruptly occurring stimulus is, by definition, not predicted and elicits immediate fear. Fear stimuli that

are predictable may also be behaviorally controlled, for example, through avoidance. Less predictable or controllable stimuli elicit more fear. However, it is only reasonable to talk about increasing fear as long as the uncontrollability does not completely undermine the coping attempts. When the situation is too uncontrollable to support active attempts to cope, fear is replaced by anxiety, and when the organism eventually gives up and becomes helpless, anxiety is replaced by depression (see **Anxiety**).

Fear Learning

Events such as obstructed breathing, physical constraints, and rapidly approaching large objects can be regarded as innate fear stimuli and may be called natural fear triggers. However, even though evolution has equipped us with defenses for a number of events that have threatened our survival in the long past of our species, modern humans, for good reason, fear many stimuli that simply were not around during our evolution. Thus, these stimuli must have acquired their fear-eliciting power through learning. They may be called learned fear triggers.

Pavlovian conditioning is the central mechanism for associative fear learning. Through Pavlovian conditioning, a natural fear trigger may transfer its potential to a new, previously neutral stimulus, thus turning it into a learned trigger. The procedure for achieving this is simply to present the two stimuli together, so that the to-be-learned trigger serves as a signal for the natural trigger. This is direct Pavlovian conditioning, but the procedure also works in a social arrangement in which one individual sees another individual express intense fear of the to-be-learned trigger. In this way, fear may transfer to new stimuli and circumstances, and, particularly for a species that has access to language, with its associative structure, this means that fear may come to be elicited from large classes of new stimuli only remotely associated with the original natural trigger.

An interesting possibility is that fear is more easily transferred to some stimuli that by themselves do not elicit fear, even though throughout evolution they have occurred in threat-related contexts. However, because of this long historic association with threats to survival, they may be evolutionarily prepared to enter easily into association with fear after only minimal aversive experience. For example, even though rhesus monkeys do not show an innate fear of snakes, they easily learn such fear after seeing conspecifics in fearful interactions with snake-related stimuli. Similar easy fear learning to neutral stimuli such as flowers is not obvious.

Pathological Fear: Phobias

Fear may sometimes be excessive to the extent that it interferes with normal adaptive functioning. Intense, involuntary, and rationally unfounded fear of a specific object or situation that provokes maladaptive avoidance is called a phobia. Phobias are classified into three categories depending on the feared object or situation.

Specific Phobias

Specific phobias concern circumscribed objects or situations, such as knives, other sharp objects, and dental treatments. One subgroup of specific phobias involves nature fears, such as fears of water or thunderstorms. Another important category centers on fear of animals; snakes, spiders, dogs, cats, and birds are typical examples. A third category involves fear of blood, taking injections, and mutilated bodies. Contrary to other anxiety disorders, which often incorporate a fear of fainting, this type of phobia is the only one actually associated with fainting as a result of a pronounced vasovagal response to exposure to the phobic situation.

Social phobias Some people tremble at the mere thought of meeting new people or having to formally address a group. In general, they fear social situations that involve being scrutinized or evaluated by others and the associated risk of being socially humiliated. Social phobia is more debilitating than specific phobia because social situations are central to human adjustment. For example, consistently avoiding such situations or enduring them only with intense dread may be detrimental both to academic and vocational careers.

Agoraphobia Agoraphobia (from the Greek *agora*, which means marketplace) denotes an intense fear of being out among people in crowded places such as in supermarkets or on public transportation vehicles. However, the fear is less concerned with this particular situation than with an intense fright of being overwhelmed by fear or anxiety in a situation in which no help or assistance is available; the common denominator is that the person would be left helpless without any escape route back to safety in the event of a sudden fear attack. Safety typically is defined as being at home, and thus many agoraphobics become captives in their homes, only able to leave if accompanied by a trusted companion.

Preparedness and Phobias

It is reasonable to assume that phobias derive primarily from learned fear triggers. Even though phobias are fairly common in the population, the

overwhelming majority does not show a phobia-level fear of, say, snakes, knives, blood, underground trains, or airplanes. Thus, the assumption that phobics somehow have associated fear to the phobic situation is readily invoked. If this were the case, we would expect a correlation between common ecological traumas and phobias. However, there is an obvious discrepancy between the distribution of phobic situations and the distribution of traumas in our environment. For example, many people have aversive experiences with broken electrical equipment, but there are few bread-toaster phobics needing clinical assistance. On the other hand, clinicians encounter many spider and bird phobics, even in environments completely lacking poisonous spiders or threatening birds. This discrepancy between traumas and phobias can be accounted for by the preparedness hypothesis because phobic objects and situations appear more obviously related to threats in an evolutionary than in a contemporary perspective. In fact, most phobic situations (animals, heights, enclosures, dominant conspecifics, lack of escape routes, etc.) have provided recurrent threats to humans and our predecessors throughout evolution. As a result, humans may have become biologically predisposed easily to associate such situations with fear even after only minimal trauma. Nonprepared situations, such as cars, on the other hand, may not come to elicit fear even after having been paired with excessive traumas.

The Neurophysiology of Fear

Research during the last 2 decades has delineated a neural network in the brain that controls fear responses and fear learning. This network is centered on the amygdala, a small set of nuclei in the anterior temporal lobe that has long been identified as a limbic structure associated with emotion.

A primary role for the amygdala appears to be the evaluation of input to the brain in terms of its potential threat. This purpose is achieved by the lateral nucleus, which receives fully processed sensory information from the cortex as well as only preliminarily processed information from subcortical structures such as the thalamus. These two routes to the amygdala have been described as the high and the low routes, respectively. Because the low route depends on monosynaptic linkage between the thalamus and the amygdala, the incompletely processed information conveyed by this route reaches the amygdala faster than the polysynaptically wired information conveyed by the high route. As a consequence, the amygdala can start recruiting defense responses even before the veridicality of the threat stimulus is confirmed by the full cortical analysis.

The high route, therefore, is not necessary for eliciting fear, but the low route may be necessary both for fear elicitation and fear learning. Fear may be elicited and learned in animals even after the ablation of the relevant sensory cortices, and in humans, fear responses can be elicited and learned via stimuli that are prevented from conscious recognition through backward masking. Thus, fear responses are recruited after a quick and nonconscious analysis of the stimulus, which explains the automatic, nonvoluntary character of intense fear, such as in phobias.

After threat evaluation in the lateral and basolateral nuclei of the amygdala, the information is conveyed to the central nucleus, which controls various efferent aspects of the fear response. Neural pathways to the lateral hypothalamus activate sympathetically controlled responses, such as heart-rate acceleration and skin conductance responses, and parasympathetically dominated responses, such as heart-rate decelerations, are influenced through the vagal motor nucleus and the nucleus ambiguus of the brain stem, which also can be controlled from the amygdala. Through connections between the central nucleus and the paraventricular nucleus in the hypothalamus, corticotropin releasing hormone can be released, which, via adrenocorticotrophic hormone from the anterior pituitary, activates corticosteroid stress hormones from the adrenal cortex. Paths to the tegmentum, including the locus coeruleus, activate the dopaminergic, noradrenergic, and cholinergic arousal systems of the forebrain, resulting in electroencephalogram (EEG) activation and increased vigilance. Overt motor responses associated with fear such as freezing, fight, and flight are activated by connections between the central nucleus of the amygdala and the dorsal

and ventral periaqueductal gray of the brain stem. The facial expressions of fear are activated through the facial motor nucleus and the seventh cranial nerve, the nervus facialis. The modulation of the startle reflex, finally, is accomplished through neurons connecting the central nucleus of the amygdala with the central nucleus for the startle reflex, the nucleus reticularis pontis caudalis in the brain stem. This circuit accounts both for peculiarities of fear activation such as its independence of conscious recognition of the fear stimulus and the complex efferent organization of the fear response. Furthermore, its sensitization through various procedures may contribute to the understanding of pathological fear and anxiety.

Afferent and Efferent Connections

The Amygdala and Fear Conditioning in Animals

The Amygdala and Fear in Humans

Glossary

Amygdala

A complex brain structure with numerous subnuclei located deep within the temporal lobe of the brain.

Backward masking paradigm

A paradigm in which an initial emotional face (e.g., fear) is presented for a very short duration (17–33 ms) and then immediately replaced by a neutral face presented for a longer duration (~200 ms). In this situation, the initial image is subliminal; subjects report that they have seen only the neutral expression.

<i>Excitatory postsynaptic potential (EPSP)</i>	A depolarization of the postsynaptic membrane.
<i>Fear</i>	An unpleasant, powerful emotion caused by anticipation or awareness of potential or actual danger.
<i>Fear conditioning</i>	A form of emotional learning in which an emotionally neutral or conditioned stimulus acquires the ability to elicit behavioral and physiological responses associated with fear after being associated with an aversive unconditioned stimulus.
<i>Long-term potentiation (LTP)</i>	The long-lasting strengthening of the connection between two neurons.
<i>Neuroimaging</i>	A number of powerful noninvasive techniques, including positron emission tomography (PET) and functional magnetic resonance imaging (fMRI), that allow the examination of regional patterns of brain activation in the living human brain with considerable spatial resolution, but limited temporal resolution, in the order of seconds as determined by vascular responses associated with neural activity.
<i>Startle response</i>	An innate reflex observed in nearly all animals, including humans, that manifests as an involuntary motor response to any unexpected noise, touch, or sight. In studies of emotion, it has been used to measure the aversiveness of emotive stimuli.

Amygdala Anatomy

The amygdala is an almond-shaped structure located deep within the temporal lobe of higher animals. It was first identified by Burdach in the early nineteenth century, who described a group of cells, or nuclei, now referred to as the basolateral complex. Subsequently, however, the amygdala was shown to be both more complex and more extended, comprising more than twelve subnuclei. In rats, current nomenclature divides the amygdala nuclei into three main groups: (1) the basolateral complex, which includes the lateral nucleus, the basal nucleus, and accessory basal nucleus; (2) the cortical nucleus, which includes the cortical nuclei and the lateral olfactory tract; and (3) the centromedial nucleus, comprising the medial and central nuclei.

Afferent and Efferent Connections

The amygdala receives input from all sensory systems: olfactory, somatosensory, gustatory, visceral,

auditory, and visual. Olfactory inputs arise at the olfactory bulb and project to the lateral olfactory tract. Somatosensory inputs pass via the parietal insular cortex in the parietal lobe and via thalamic nuclei to the lateral, basal, and central nuclei. Primary gustatory and visceral sensory areas project to the basal nucleus and central nucleus. In contrast, auditory and visual information, thought to be important in fear conditioning, arise from association areas rather than from the primary sensory cortex.

The amygdala has widespread efferent connections to cortical, hypothalamic, and brain-stem regions. The basolateral complex projects to the medial temporal lobe memory system (e.g., the hippocampus and perirhinal cortex), and the basal nucleus has a major projection to prefrontal cortex, nucleus accumbens, and the thalamus. Thus, the anatomy of the amygdala is consistent with its role in fear processing. The amygdaloid complex receives inputs from all sensory modalities and activates brain regions important to measurable neurobehavioral correlates of fear. How it works offers an insight into the nature of emotion in humans and animals.

The Amygdala and Fear Conditioning in Animals

Much of the scientific interest in the amygdala stems from its established role in fear conditioning, research that has been carried out mostly in rats. Classical Pavlovian fear conditioning is a type of emotional learning in which an emotionally neutral conditioned stimulus (CS), often a tone, is presented in conjunction with an aversive unconditioned stimulus (US), typically a small electric shock to the foot of the animal. After one or more pairings, the emotionally neutral stimulus (CS) is able to elicit a constellation of species-specific conditioned responses (CRs) that are characteristic of fear, such as freezing or escape behavior, autonomic responses (elevated heart rate and blood pressure), potentiated acoustic startle to aversive acoustic stimuli, and increased neuroendocrine responses (release of stress hormones). Fear conditioning therefore allows new or learned threats to activate ways of responding to threat that have been long established in evolution.

Numerous studies have demonstrated that lesions to the amygdala impair the acquisition and expression of conditioned fear in rats. The basolateral complex of the amygdala is a substrate for sensory convergence from both the cortical and subcortical areas, and it is considered a putative locus for CS-US association during fear conditioning. Thus, its cells encode this emotional learning. By contrast, the central nucleus of the amygdala projects to brain

regions implicated in the generation of fear responses, such as the hypothalamus; it may therefore act as a common output pathway for the generation of fear-conditioned responses. Consistent with this hypothesis, lesions to either the basolateral or central nucleus of the amygdala impair the both the acquisition and expression of conditioned fear.

The amygdala pathways involved in fear conditioning have also been studied using electrophysiological studies (see [Figure 1](#)). During fear conditioning, the convergence of CS and US inputs to the basolateral complex results in sustained enhancement, or long-term potentiation, of EPSPs evoked by the CS ([Figure 1](#)). Thus, the amygdala is able to both integrate and associate sensory information and influence the motor and physiological responses associated with fear conditioning.

The Amygdala and Fear in Humans

Evidence from Lesion Studies

Damage to the amygdala, or areas of the temporal lobe that include the amygdala, also produces deficits in fear processing in humans. In a recent study, a patient with Urbach–Wiethe disease (S.M.), a rare congenital lipid storage disease that results in the bilateral degeneration of the amygdala, underwent fear conditioning with either visual or auditory CSs and a loud noise as the US. Compared to normal control subjects, S.M. showed no evidence of fear conditioning (as measured by galvanic skin response). Notably, S.M.'s recall of events associated with fear conditioning was intact. These data support the hypothesis that the amygdaloid complex plays a key role in the acquisition of Pavlovian fear conditioning, whereas the hippocampus is important in acquiring declarative knowledge of the conditioning

contingencies. In a further study with the same patient, it was demonstrated that bilateral amygdala damage impaired the recognition of fearful facial expressions. Other patients with Urbach–Wiethe disease have also been shown to be impaired in recognizing fearful facial expressions. S.M., however, had no difficulty in recognizing people by their faces or in learning the identity of new faces. These results suggest that the human amygdala is directly involved in the processing of emotion but not in recognizing aspects of facial appearance. There is also evidence to suggest that the impairment of the perception of expressive signs of fear in patients with amygdala damage extends beyond facial expressions; bilateral amygdala damage has also been associated with impairment in the recognition of vocalic expressions of threat.

The effect of amygdala damage on the startle response has also been studied in humans. A recent study compared the startle response in a 32-year-old male with a localized lesion in the right amygdala with that of eight age-matched controls. The control subjects displayed the well-documented effect of aversive stimuli potentiating startle magnitude. In the patient with the right-amygdala lesion, no startle potentiation was observed in response to aversive versus neutral stimuli. Together, studies of patients with amygdala damage suggest that this structure plays a key role in the perception and production of negative emotions, particularly fear.

Evidence from Neuroimaging Studies

During the early 1990s, researchers began to explore the role of the amygdala in fear processing using neuroimaging (e.g., positron emission tomography, PET; and functional magnetic resonance imaging, fMRI) and continue to do so today. So far, amygdala activity has been assessed predominantly using two

Figure 1 During fear conditioning convergence of inputs (CS and US) induce long-term potentiation of EPSPs evoked by the CS. a, Schematic; b, graphs. CS, conditioned stimulus; EPSPs, excitatory postsynaptic potentials; US, unconditioned stimulus.

basic paradigms: fear conditioning and presentation of emotional facial expressions.

Functional MRI experiments have demonstrated increased amygdala activity during both the early acquisition and early extinction of fear conditioning to a visual stimulus. Indeed, it has been suggested that the amygdala's role is limited to early conditioning or early extinction, when response contingencies change. That is, the amygdala is particularly important for forming new associations as relationships – emotional learning and unlearning.

The amygdala may also be responsible for generating coordinated reflexive behavioral responses to highly aversive stimuli. The animal literature shows that the amygdala, specifically the central nucleus, generates conditioned autonomic, behavioral, and endocrine responses in acute stress paradigms. CSs, which may be interpreted as changing the animal's emotional set, increase the response in startle paradigms, for example. Clearly, this kind of response may be quite primitive, but lesioning experiments demonstrated definite mediation by the amygdala. It is usually assumed the amygdala may be involved in the selection of more purposive motor-behavioral responses in response to more subtle aversive conditions.

The second major neuroimaging protocol for assaying amygdala activity is the presentation of faces expressing different emotions. It is difficult to over-emphasize the importance of facial expressions in social communication. Facial expressions act at a number of levels to signal important information; expressions of disgust enable the avoidance of the ingestion of harmful substances, and fearful facial expressions rapidly communicate the presence of imminent threat. More subtly, cues from the faces

of others are continuously informing us of our social impact and acceptability, and we, in turn, communicate our feelings and intentions through our own facial gestures and expressions.

It is no surprise, therefore, that facial expressions have provided a useful experimental tool to measure fear-related amygdala activity. Many studies have demonstrated that the amygdala is preferentially activated during the presentation of fearful facial expressions. Moreover, even when subjects are unaware of seeing a fearful face, by the use of a masking protocol or when attention is directed away from the fearful face, the amygdala is still activated. Such findings suggest that the extraction of potentially threatening information within the amygdala may not be sufficient for conscious face perception but it may well be necessary. The amygdala may act to direct attention toward emotionally salient events that are ambiguous or require further processing. Indeed, anatomical studies in rats suggest that sensory information travels to the amygdala via two distinct pathways: a short, rapid thalamic route, and a longer cortical pathway. It is proposed that the short thalamic pathway rapidly prepares the animal for a potentially aversive encounter independent of conscious processing, which occurs later via the slower cortical route. A similar two-way route to the amygdala has yet to be anatomically defined in humans; however, evidence from a number of well-designed fMRI experiments point to the existence of these two pathways ([Figure 2](#)). First, as already described, the amygdala responds to fearful faces even when presented outside conscious awareness. Second, in an extension of the masking paradigm, Whalen and colleagues presented degraded versions of fearful and happy expressions

Figure 2 Two-pathway hypothesis for amygdala activation to fear. The short, rapid thalamic route is shown by the dashed arrow; the longer cortical pathway is shown by bold arrows. (For clarity, subcortical structures are shown overlaid on brain surface.)

by displaying only the eye whites immediately masked by a complete image of a neutral expression. Fearful faces are typically associated with the enlarged exposure of the sclera, and it was observed that the crude information provided by the wide eyes of fearful expressions was sufficient to stimulate the amygdala. Analogously, Vuilleumier and coworkers used fMRI to compare amygdala and cortical responses to rapidly presented (200 ms) fearful and neutral faces that had been filtered to extract either low-spatial-frequency information (giving a blurry image) or high-spatial-frequency information (giving a finely detailed, sharp image) (Figure 3). As detected by fMRI, the finely detailed images elicited a greater response in a region of the cortex called the fusiform face area, a brain region widely implicated in the conscious recognition of faces and facial expressions. The amygdala was relatively unresponsive to these images even if they were fearful in nature. Low-spatial-frequency fearful faces, however, produced a robust response in the amygdala. Although these findings could imply the existence of a two-pathway route to the amygdala in humans, with dissociation between neural responses in amygdala and fusiform gyrus across different spatial frequency ranges for face stimuli, they do not prove it. However, they suggest that the amygdala does not require very complex configurational stimuli, such as presented by the complete image of a face, in order to respond to emotion. It is obviously possible that crude fragmentary information related to emotionally salient signals could be rapidly communicated via a subcortical route. Extreme facial expressions of emotion may be well adapted to attract immediate attention via this mechanism.

Given the involvement of the amygdala in fear processing, there is increased interest in the role of this structure in anxiety disorders, such as post-traumatic stress disorder (PTSD), and obsessive-compulsive disorder (OCD), and in depression. For example, patients with PTSD show increased blood flow in the right amygdala (as measured by PET) in response to the presentation of images designed to activate traumatic memories, compared to neutral images. Using fMRI, it has also been demonstrated that individuals with OCD have significantly increased activity bilaterally in the amygdala in response to ideographically tailored stimuli designed to provoke their symptoms.

Functional MRI can also be used to investigate how pharmacological treatment for anxiety and depression modulates amygdala activity. A number of studies have demonstrated that the increased amygdala response to negative facial expressions seen in depression is reduced following effective treatment with serotonergic antidepressants. Although these results suggest an important role for the amygdala in the recovery from depression, it remains unclear if this normalization of amygdala response to fearful faces with time is a direct action of the drug or, rather, a reflection of the current symptom state (the scans of patients when depressed and when they had recovered were compared). Work from our laboratory, in healthy volunteers, demonstrated that the short-term administration (7 days) of either serotonergic (e.g., citalopram) or norepinephrine (e.g., reboxetine) antidepressants reduces the amygdala response to the masked expressions of fear compared to placebo controls. Significantly, these effects on the amygdala were observed in the absence of changes in mood. These

Figure 3 Processing of images by the amygdala and cortical regions. a, Low-frequency image; b, finely detailed image. The rapid subcortical pathway may allow low-frequency inputs to reach the amygdala rapidly, whereas finely detailed images are further processed in cortical regions (e.g., fusiform gyrus).

results suggest that antidepressants have rapid, direct effects on the amygdala. Moreover, if similar effects are seen in clinical populations, drug modulation of amygdala activity in response to negative stimuli may be a key component in patients' recovery from depression and anxiety.

Introduction

Thermal Control in Endotherms

Endogenous Pyrogens and Fever Induction

Stress and Fever Induction

Glossary

<i>Anterior hypothalamus/preoptic area</i>	Hypothalamic area representing the major center of control of the temperature set point of the body.
<i>Basal metabolic rate</i>	The minimal (or steady state) energy use, keeping the body temperature constant under conditions of no net work carried out.
<i>Cytokines and interleukins</i>	Small proteins with regulatory functions produced and secreted mostly by immunocompetent cells.
<i>Endogenous pyrogens</i>	Proinflammatory cytokines or endogenous compounds that function as humoral mediators of fever induction.

Hypothalamic-pituitary-adrenocortical axis

The central and peripheral system sustaining the physiological response to stressors.

Intraperitoneal and intracerebroventricular injections

Usual ways to administer exogenous pyrogens, i.e., lipopolysaccharide or endogenous pyrogens to study their peripheral and central proinflammatory effects.

Lipopolysaccharide

A fraction of the *Escherichia coli* bacterial wall used in different experimental models of gram-negative bacterial infection.

Thermoneutral zone

A range of ambient temperatures compatible with a control of the core body temperature achievable solely by cardiovascular changes in the peripheral compartment of the body.

Introduction

Fever is a transient change of the hypothalamic temperature (HT) set point causing the rise of the core body temperature (BT) of about 2–4°C in humans. This physiological response to inflammatory stimuli is always associated with peripheral and central events: massive hepatic production of acute-phase proteins, sleep induction, and anorexia, defined globally as the acute-phase response. Fever is triggered by the peripheral and central production of interleukin-1β (IL-1β),

tumor necrosis factor α (TNF- α), and interleukin-6 (IL-6) and is caused by the local production of prostaglandins (PGE₂) in the anterior hypothalamus/preoptic area (AH/POA). The rise of the BT during febrile response is achieved by reducing heat loss (vasoconstriction) and by increasing simultaneously the heat production (facultative thermogenesis) via the activation of the sympathetic system. The sudden heat production associated with acute stress, usually described as hyperthermia, is also triggered by the activation of the sympathetic system. It is a common observation that subchronic, chronic, or exhaustive stresses are associated either with fever-like episodes or with an impairment of the whole inflammatory response. Experimental data demonstrate the endogenous production of IL-1 β in rat hypothalamus during unescapable stress, pointing to the tight molecular control exerted by glucocorticoids (GCs) and corticotropin-releasing factor (CRF) on the production and effects of pyrogenic cytokines.

Thermal Control in Endotherms

Heat production is a sign of metabolic activity. Heat storage/heat exchange mechanisms are strikingly different in living organisms, resulting from the evolution of specialized systems (e.g., enzymes, organs, and cell types) required to survive and acclimate in

different environmental conditions. **Figure 1** shows a summary of the mechanisms controlling thermal balance in endotherms. The core BT is the result of both heat production and heat exchange with the environment under the control of different pools of thermal sensors present in skin, viscera, main cardiovascular districts, spinal cord, and brain. The whole body can be divided in three main compartments (core, periphery, and skin), which regulate the exchange of heat mainly by modifying blood flow in the different districts. Cardiovascular, respiratory, and perspirative effects are always accompanied by behavioral changes in order to obtain an effective increase or drop of the BT. The main metabolic exothermic reactions contributing to heat production are listed in **Figure 1b**. The brown fat tissue (BAT), which is very rich in mitochondria, can produce heat by uncoupling the electron transport/proton gradient in the inner mitochondrial membrane thanks to the presence of uncoupling protein-1 (UCP-1) (nonshivering thermogenesis). Other gene products of the same family, UCP-2 and UCP-3, are expressed in white fat tissue/liver and in the muscular tissue, respectively. The contribution of UCP-2 to thermogenesis during fever is under debate.

Transient (or prolonged) temperature changes, observed during fever, have a deep metabolic impact, being associated with kinetic changes in all enzymatic reactions, in membrane conductance, and change

ATP, adenosine triphosphate; GTP, guanosine triphosphate; NADPH, nicotinamide adenine dinucleotide phosphate; RNA, ribonucleic acid.

Figure 1 Schematic view of the mechanisms of heat production and heat exchange in endotherms. (a) Conduction, convection, radiation, evaporation, and metabolic heat production contribute in an additive manner to the definition of the temperature in the different districts of the body: skin, periphery, and core. The mechanism of selective brain cooling controls the facial venous flow in order to locally control the brain temperature by circulatory means. (b) The main exothermic metabolic reactions.

of permeability of ionic channels. Furthermore, to actively increase the BT of a human by 1°C within 1 h requires the net heat storage of about 3.48 J kg^{-1} with an energy cost for a human of 70 kg (in thermoneutral conditions) of about 243.6 J. GCs do support the metabolic heat requirements of the febrile response by enhancing several thermogenic reactions. Endogenous pyrogens (EPs) are also responsible for the metabolic changes observed during the acute-phase response. In particular leptin, a protein controlling white fat tissue metabolism and energy expenditure, exerts a necessary role in sustaining facultative thermogenesis during fever. Considering the energy required to mount a febrile response, it becomes understandable why starvation, cachexia, extreme ambient temperature, or other causes of metabolic distress would reduce the magnitude of the febrile response if not abolish it completely.

Temperature Set Point

Figure 2 shows effector systems activated in endotherms to keep the core BT constant while the ambient temperature changes progressively. During cold exposure, shivering is controlled by the activation of the motor system, whereas changes in superficial microcirculation and nonshivering thermogenesis are signs of the activation of the sympathetic system. The energetic requirement of the cold-induced thermal

response is reduced progressively as the ambient temperature reaches the thermoneutral zone. Within this narrow range of temperatures, energy requirements to keep the BT constant (in absence of stress and motor activity) are met by the basal metabolic rate (BMR). The response to a warm environment is conversely characterized by vasodilatation, panting, and sweating. Shivering frequency and BMR are inversely correlated on a logarithmic scale with the body mass. Furthermore, the BMR is constantly adapted in different individuals in response to climatic conditions, diet, and motor activity under the control of the thyroid hormones. The BT in the different compartments and the range of temperatures triggering the effector systems in order to increase alternatively heat storage or heat loss are defined by the integration of thermoafferent signals and their comparison with a temperature set point defined in the AH/POA. Among the signals integrated in AH/POA, it is important to point at the local HT, reported by several studies as the stimulus able to overcome peripheral inputs. The local HT cannot fluctuate freely more than $0.1\text{--}0.2^{\circ}\text{C}$ in a narrow range of temperatures that is defining the set point. Whatever change of the local temperature outside the limits of this range would trigger the effector response to a warm or cold environment (Figure 2). During fever the hypothalamic set point is shifted upward with a

Figure 2 Thermal control in endotherms: the sympathetic and parasympathetic systems are alternatively activated by changes of the ambient temperature exceeding the thermoneutral zone in order to keep the core BT constant. The thermoneutral range is defined by the HT set point. The whole system is transiently shifted upward during fever.

reset of the range of HTs triggering the different effector responses. Because the body would need increased heat storage and heat production to reach the new temperature in the different districts, fever, in its initial phase, would cause a thermal response mimicking the normal reaction to a cold environment.

Thermosensitive Neurons

There are no known molecular markers for the neurons involved in the central control of the temperature set point. The only information available about the neuronal populations involved is that they share the common feature of being thermosensitive. Neuronal thermosensitivity (TS) can be characterized by measuring the neuronal firing rate in a parapsycho-physiologic range of temperatures and calculating the thermal coefficient for each cell. The range of thermal sensitivity of AH/POA neurons may vary quite extensively and it is generally linear within a narrow range of temperatures. Two distinct populations of TS neurons have been characterized in the hypothalamus: cold-sensitive and warm-sensitive neurons. Cold-sensitive neurons are less studied, mostly because they represent less than 10% of the TS neurons in AH/POA. Warm sensitivity has been studied quite extensively using hypothalamic slices. These studies demonstrate that TS is an intrinsic cellular property. Warm-sensitive neurons are present in several brain regions: in AH/POA, in lower centers in the brain stem, and in the spinal cord. The presence of TS neurons in different brain regions may suggest temperature differences in the cerebral versus peripheral compartment. However, it has been demonstrated that thermal curves are similar both in time course and in absolute values in the cerebral cortex and the peritoneum under basal conditions, during fever, and pharmacological hypothermia.

Fever and Thermosensitivity

Fever depresses the TS of neurons whose firing rates had been increased previously by local AH/POA warming. Furthermore, local injections in the AH/POA of EPs or prostaglandin E₂ (PGE₂) cause a reduction of the tonic firing of warm-sensitive neurons similar to the one observed when lowering locally the HT. The plasticity of warm-sensitive neurons and their responsivity to bath-applied IL-1 or IL-6 has yet to be characterized properly, and moreover, the molecular components of neuronal activity changes in AH/POA during fever have yet to be determined. Few studies reporting intracellular recordings from warm-sensitive neurons are opening up a key path of research in this respect.

Endogenous Pyrogens and Fever Induction

IL-1 β was among the first cytokines described, and its biological properties as EP, the leukocytic pyrogen, were described long before the purification of the protein. In general, the concept of a humoral mediator of a fever response is older than the discovery of pro-inflammatory cytokines and was initially related to the observation that bacterial debris lipopolysaccharide (LPS) could cause fever with almost a 2-h delay from the time of the injection. The LPS effect was also characterized by priming and tolerance, further suggesting the presence of endogenous mediators. The progressive discovery of several pyrogenic cytokines present in the plasma only during an inflammatory reaction, and the study of their synergism and production in hypothalamus during a febrile response, further clarified the definition of EP. All EPs cause fever when administered by the intracerebroventricular (ICV) route and in the periphery and they are released into the circulatory system during the fever response to exogenous pyrogens. The magnitude and time course of the fever response could be related to the plasma and hypothalamic levels of the EP only in the case of IL-6. IL-1 β or TNF- α seems to trigger the febrile response more than sustaining it because several endogenous antagonistic systems (such as IL-1 receptor antagonist (IL-1ra), in the case of IL-1 α and IL-1 β) are buffering or suppressing *in vivo* the initial EPs effects both peripherally and centrally (Figure 3a). The list of known EPs would then contain interferons (IFN- α , - β , and - γ), IL-1 α / β , TNF- α / β , and IL-6. IL-1 β is the most potent: a 30-ng kg⁻¹ intravenous injection is sufficient to cause fever in humans. IL-6 and chemokines (IL-8, macrophage inflammatory protein-1) would trigger the fever response only when injected centrally into the AH/POA or ICV. The generation of mice carrying null mutations for the different EPs or their receptors has been extremely important in demonstrating the presence of a hierarchy of EP in the generation of the fever response, with IL-6 acting probably downstream of IL-1 β and TNF α .

The most relevant results of the studies can be summarized as follows:

- Studies on IL-1 type 1 receptor (IL-1RI) knockout (KO) mice and IL-1R accessory protein (IL-1Rap) KO mice have demonstrated that IL-1RI mediates the fever response induced by an intraperitoneal (IP) injection of IL-1 α and IL-1 β . The fever response to LPS is rather normal in these animals, suggesting that TNF and other EPs can bypass the IL-1 system in the generation of the febrile response.

Figure 3 (a) Fever response in rats injected IP with $5 \mu\text{g kg}^{-1}$ of recombinant human IL-1 β . The febrile response is blocked by the injection of recombinant human IL-1ra (2.5 mg kg^{-1}). (b) Fever response in rats injected IP with human recombinant IL-1 β ($5 \mu\text{g kg}^{-1}$). The effect is blocked by the previous injection of the nonpeptidic CRF receptor antagonist CP154,526 (0.16 mg kg^{-1} , IP). Data are means $\pm$ standard error means. Data were recorded using a telemetry system and averaged every 30 min. Open circles, IL-1ra plus IL-1 β ($n = 5$), closed circles, IL-1 β ($n = 3$), open squares, CP154 526 plus IL-1 β ($n = 4$), and closed squares, IL-1 β ($n = 8$).

- IL-1 β KO mice show hyperresponsive fever mostly in terms of magnitude of the effects in response to IL-1 α and IL-1 β IP injection.
- IL-6 KO mice are unable to mount a febrile response on injection of IL-1 β or LPS in the periphery. Only the parallel co-injection of IL-6 IP seems to restore a sort of fever response to LPS IP injection. Very interesting genetic studies on different autoimmune familiar disorders like Mediterranean fever are pointing future research towards proteins such as pyrin and cryopyrins which are possibly upstream EP production.

Exogenous Pyrogens

The most used experimental model of fever response in the presence of an endogenous stimulus is represented by LPS injection in the periphery. This model mimics a response to gram-negative bacterial infections. Fever is also present during gram-positive bacterial infections because macrophages can produce somnogenic and pyrogenic muramyl peptides during the digestion of staphylococci fractions. Furthermore, agents such as turpentine are broadly used as an experimental model of aseptic inflammation, which is almost uniquely mediated by IL-1 β . However, the broadest spectrum of exogenous pyrogens is offered by viral proteins 2 or by the etiological agents of parasitic infections such as schistosomiasis or malaria. In case of viral infections, interferons (IFNs) are the principal responsible of the observed febrile response with IL-1 β contributing as EP. EP and Toll-like proteins responsive to exogenous pyrogens are probably present in all vertebrates. Equally ancient from the

phylogenetic point of view is the complement cascade of proteins which interact with EPs and EP production mainly via anaphylatoxins.

Expression of Endogenous Pyrogens and their Receptors in the Hypothalamus

IL-1 α/β , TNF- α , and IL-6 gene expression can be induced in AH/POA on peripheral immune challenge (with LPS or IL-1 β for instance). The peripheral administration of LPS induces IL-1 β production in meninges, choroid plexus macrophages, some perivascular cells, and microglial cells shortly after IP injection (1–8 h). Constitutive expression of IL-1 β and IL-6/IL-6R in neuronal cell types has been reported by some authors, but the matter is still controversial. Receptors for the different EPs, particularly IL-1RI, are expressed constitutively in AH/POA. Their expression is modulated by GCs and EP, particularly IL-1 β . At the same time, pharmacological doses of corticosterone block the LPS-induced fever response and IL-1 α/β and TNF- α mRNAs expression in the hypothalamus, suggesting a causal role for the hypothalamic production of cytokines in fever induction. The control by GC and EPs on the expression of EPs/EP receptors is mostly transcriptional. The promoter regions of EP genes contain an unusually high number of GC receptor response elements. In the case of IL-1 β and TNF- α , posttranscriptional control of GC at the mRNA and proteic level has been demonstrated to be extremely important in controlling the cellular production of these EPs in immunocompetent cells and the activation/secretion of the mature form of these cytokines.

Humoral Versus Neuronal Mediators of Fever Induction

How does the brain sense EPs? This key question has several answers. In fact, circulating pro-inflammatory cytokines can reach the brain via the interaction with saturable carriers in the plexus chorioideus. However, this mechanism would account for the entrance of a limited amount of protein, eventually able to trigger local cytokine production AH/POA. Several pathologic conditions cause damage to the blood-brain barrier. In this case the amount of circulating EPs reaching the hypothalamus could be higher. There is also a specialized circumventricular organ, the organum vasculosum lamina terminalis (OVLT), located along the margin of the ventricular system that has fenestrated capillaries and, therefore, direct contact with the circulatory system. The role of the OVLT has been demonstrated in the case of peptides such as angiotensin II and cholecystokinin and is probably also essential for the transduction of the plasmatic levels of EPs into central effects. A third mechanism of immune signaling, essential in the case of peritoneal immune challenge, is the peripheral stimulation of sensory nerves, particularly the afferent part of the vagus nerve. IL-1Rs are present in vagal paraganglia, chemosensory bodies, all along the course of the vagal nerve in the cervical region, and in thoracic and abdominal cavities. Subdiaphragmatic vagotomy is able to block the central production of IL-1 β in response to the IP injection of IL-1 β or LPS. The immediate c-fos mRNA induction has been used to trace the neuronal pathway activated in response to the peripheral loading of LPS, and several studies would point to the presence of a selective activation of neurons in the hypothalamus (paraventricular nucleus, ventromedial POA), brain stem (A1 and A2 region), nucleus of the solitary tract, and ventrolateral medulla. In some cases the activated pathways represent antipyretic responses that are initiated during fever, such as the activation of neurons that contain α -melanocyte-stimulating hormone (α -MSH) and arginine-vasopressin.

Role of Prostaglandins in Fever

The role of prostaglandins (PG) of the E series in fever induction was first described by Milton and colleagues in 1970. PGs of the F class can also cause fever. Their effect is, however, mediated by the release of CRF. Both PG series are thus EPs. The fever response triggered by pro-inflammatory cytokines is always mediated by the local production in AH/POA of PGs. In fact, the pyrogenic effect of peripheral LPS and EPs can be blocked by cyclo-oxygenase inhibitors injected locally into AH/POA. A dense distribution

of PGE₂-binding sites is present in the anterior wall of the third ventricle surrounding the OVLT in the rat brain. Moreover, a study on mice carrying a null mutation for the different PG receptors demonstrated that receptor EP3 selectively mediates the PGE₂-induced fever response in the presence of IL-1 β or LPS. It is important to note that PG synthesis inhibitors are excellent antipyretic agents but have few or no effects on stress. So the picture is not complete. A missing link for fast hypothalamic events triggered by EPs could be the C2-ceramide pathway.

Stress and Fever Induction

Stress-induced fever can be measured using several experimental protocols of stress in rodents, e.g., unescapable stress or restriction. In some cases, it should be noted, however, that the stress response would modify the circadian rhythms of BT and that the results obtained should be normalized considering possible shifts of the circadian rhythm of the BT of the animals. The development of a fever response to certain kinds of stress is also confirmed by the increased expression in the hypothalamus and hippocampus of EPs; particularly IL-1 β mRNA and protein. The effects of IL-1 β on all the levels of the hypothalamus-pituitary-adrenocortical (HPA) axis are significant and very well characterized by several studies. IL-1 β can activate CRF synthesis and release and adrenocorticotrophic hormone (ACTH) secretion acting locally at the hypothalamic and pituitary level, respectively. Hence, IL-1 β is one of the few known agents able to induce CRF release, although the direct effect of IL-1 β on the production/release of GC is still controversial. In contrast, the GC effect on cytokine production is dual and depends on the circulating levels of GC. In fact, physiological levels of GC would support the metabolic requirement of the acute-phase reaction, leading also to increased GC production as the HPA is activated. As a result, the increased GC release during inflammation buffers the pro-inflammatory cytokine effects by restricting their expression. A special note should, however, be taken while discussing the effect of GC on IL-6. In rodents, IL-6 mRNA expression is higher in the hypothalamus after chronic treatment with high doses of corticosterone, and mice overexpressing IL-6 in astrocytes exhibit higher plasmatic levels of corticosterone, reduced ACTH response, and adrenal hyperplasia. This may suggest a direct effect of IL-6 at the level of the adrenal glands. Furthermore, both IL-6 and GC are responsible for the production of different sets of hepatic proteins carrying GC-responsive elements and nuclear factor-IL-6 response elements in the promoter region of their genes, and

they are both probably involved in controlling the duration and the magnitude of the acute-phase response. Increased plasmatic cytokine levels during stress have been explained considering the possible bacterial translocation from the gastrointestinal tract to the mesenteric lymph nodes.

The presence of this phenomenon is, however, seldom considered when planning an experimental protocol, and the impact of bacterial translocation on central and peripheral IL-1 production has not yet been characterized clearly. When examining the activation of the HPA axis during fever response, it is important to keep in mind that a central role is played by CRF and vasopressin. Central injection of CRF causes fever in rats and it also activates thermogenesis in the BAT. Furthermore, neutralizing antibodies to CRF or synthetic CRF antagonists block the pyrogenic response associated with IL-1 β or TNF injection ([Figure 3b](#)). CRF plays a necessary but indirect role in the development of the fever response. Vasopressin is an endogenous antipyretic hormone. New synthetic selective antagonists will possibly allow in the future a better understanding of which receptor is mediating fever and HPA-axis effects.

Finally, the role of the sympathetic system in the development of stress or the cytokine-induced thermal response has to be redefined on the basis of the demonstrated presence of the constitutive production of IL-1 β and IL-6 in the sympathetic ganglia and in adrenal medulla. *In vivo* during an inflammatory reaction and fever induction, the presence of EP and EP receptors at different levels can ensure a tight control on the activation of the sympathetic system in terms of magnitude and duration of the effect based on the presence of a local or systemic inflammatory reaction.

Conclusion

Glossary

<i>Allostasis</i>	Maintaining stability (or homeostasis) through change; term introduced by Sterling and Eyer in 1988 to describe cardiovascular adjustments to resting and active states.
<i>Homeostasis</i>	The maintenance of equilibrium, or constant conditions, in a biological system by means of automatic mechanisms (generally feedback systems) that counteract influences (stressors) that tend toward disequilibrium (term introduced by Walter Cannon in 1932).
<i>Hypercortisolemia</i>	Excessively high concentrations of adrenal corticosteroids in plasma.
<i>Hypophyseal portal vessels</i>	A group of small venules that connect a primary plexus of capillaries in the median eminence of the hypothalamus (base of the brain) with a secondary plexus of sinusoids in the pituitary gland. Blood flowing in these vessels,

which run down the pituitary stalk, transports hypothalamic-pituitary regulatory neurohormones, released at nerve terminals in the median eminence of the hypothalamus, to the anterior pituitary gland, where they stimulate or inhibit the release of anterior pituitary hormones.

Limbic system

An extensive brain region that includes the cingulate and parahippocampal cortex, hippocampus, amygdala, hypothalamus, septal nuclei, and other structures. The precise interaction of the several components of the system is poorly understood, but since the proposal by Papez, the limbic system has been implicated in emotion. The connections between the limbic system and the neocortex, hypothalamus, and the olfactory bulb via the olfactory tract suggest that it serves as an important analyzer-integrator of signals, which it conveys from the neocortex to the hypothalamus. The input of olfactory information to the limbic system has led to its alternative name, the rhinencephalon (olfactory brain), and possibly reflects the strong emotive and signaling effects of smell in many animals. The structure and relative size of the limbic system have remained remarkably constant through evolution; in humans it is overshadowed by the massive development of the neocortex.

Neurohormones

Chemical neurotransmitters released from nerve terminals into the hypophyseal portal vessels or the systemic circulation at neurohemal junctions and conveyed to their target cells by the blood stream. This contrasts with classical neurotransmitters that reach receptors on target cells by crossing synaptic clefts or neuromuscular junctions.

Suprachiasmatic nuclei

Two small hypothalamic nuclei located immediately above (dorsal to) the optic chiasm that are responsible for regulating most circadian rhythms of the body.

Introduction

Feedback control systems are fundamental for the normal physiological functioning of the body. There are two types of feedback, negative and positive, of which the former is the more common. Removal of the main pituitary target glands, the adrenals, gonads, and thyroid, the most reproducible and reproduced

experiment in classical endocrinology, demonstrates that the secretion of pituitary adrenocorticotropin (ACTH), gonadotropins, and thyrotropin is controlled by negative feedback exerted by the adrenal corticosteroids, gonadal steroids, and thyroid hormones, respectively. Interruption of the negative feedback loop caused, for example, by surgical or pharmacological adrenalectomy, gonadectomy, or thyroidectomy, or an enzymatic defect in steroid or thyroid hormone biosynthesis, results in massive hypersecretion of pituitary ACTH, gonadotropin, or thyrotropin.

Crucial for homeostasis, negative feedback control mechanisms are composed of a system in which the output moderates the strength of the controller to a predetermined set point level (Figures 1 and 2). The set point–stimulator complex contains a comparator (error detector), which compares the strength of the feedback signal with a preset level. An increase in the strength of the feedback signal above the preset level reduces the output of the stimulator, whereas a decrease in the strength of the feedback signal below the preset level results in an increase in output of the feedback signal and corrects the error. Negative feedback control operates widely throughout the body at the molecular (e.g., end product inhibition of enzyme activity), cellular, and whole system/body levels. The mechanisms by which the set point is determined vary between systems: in the case of the hypothalamic-pituitary-adrenocortical (HPA) feedback system, the set point is regulated by the central nervous system. GABAergic and glutamatergic neural projections from the limbic system and other brain

regions to the paraventricular nuclei (PVN) of the hypothalamus may play a key role in HPA set point regulation.

Positive feedback, whereby the output of a system increases the output of the stimulator (gain in the system) (Figure 2b), is far less common than negative feedback, possibly because taken to its logical conclusion, a positive feedback system, uncontrolled, will eventually self-destruct. Some systems loosely termed positive feedback are, in fact, servomechanisms. A servomechanism is a closed loop control system, which increases significantly the power of a small signal. Positive feedback is exemplified by (1) estrogen stimulation of gonadotropin secretion, which results in ovulation, and (2) the release of oxytocin induced during parturition by pressure of the fetal head on the uterine cervix. The latter triggers volleys of impulses that, by way of a multisynaptic pathway to the hypothalamus, stimulate oxytocin release. Oxytocin stimulates further contraction of the uterus, which results in a further increase in pressure on the uterine cervix. This vicious cycle is broken only when the fetus is expelled. Servomechanisms are illustrated by the way that, just before ovulation in humans as well as in other spontaneously ovulating mammals, elevated plasma estrogen concentrations increase the responsiveness of the anterior pituitary gland to gonadotropin-releasing hormone (GnRH) by 20- to 50-fold. This estrogen effect, reinforced by the priming effect of GnRH, whereby a small pulse of GnRH further potentiates pituitary responsiveness to itself, ensures the occurrence of a massive ovulatory gonadotropin

Figure 1 A generalized feedback control system. Modified from Milhorn, H. T. J. (1966). *The application of control theory to physiological systems*, with permission from Saunders, Philadelphia, PA.

Figure 2 (a) Negative feedback minimizes the disturbance to a regulator, resulting in a system in which the output tends to remain constant. In this case, the ratios of the decrements of the controlled variable C (C_2/C_1 , C_3/C_2) are less than unity. (b) In positive feedback (left-hand curves) an initial disturbance results in a continuous increase in output (vicious cycle). The increments of the controlled variable (C_2/C_1 , C_3/C_2) are greater than unity. When the response does not result in a vicious cycle, the ratios of C_2/C_1 , C_3/C_2 , and so on are less than unity (see right-hand curves in B). From Milhorn, H. T. J. (1966). *The application of control theory to physiological systems*, with permission from Saunders, Philadelphia, PA.

surge in response to a small surge or increased pulse frequency of GnRH.

This article focuses on the principles of negative feedback control in the HPA system with emphasis on neurohormone and hormone release. While the discussion concentrates on negative feedback maintenance of homeostasis, the same mechanisms are involved in allostasis that is brought about by a change in set point so as to enable the organism to deal with the physiological challenge or stress.

Overview

In the normal state, with the negative feedback loop intact, the set point in the brain-pituitary module maintains the secretion of ACTH within a relatively narrow bandwidth. Within this bandwidth, the basal secretion of ACTH is pulsatile. Plasma ACTH concentrations also show a circadian rhythm, with a peak in the morning and a trough approaching a nadir around midnight. In nocturnal animals, such as rodents, the phase of this rhythm is reversed so that plasma ACTH concentrations reach a peak just before the onset of darkness. The circadian rhythm of ACTH results in a circadian rhythm in the plasma concentrations of adrenal corticosteroids: cortisol in

humans and corticosterone in rodents. A key feature in both diurnal and nocturnal animals is that corticosteroid plasma concentrations reach a peak just before the animal is due to wake from sleep; the levels are lowest just before or during sleep.

Glucocorticoids (cortisol in the human; corticosterone in rodents) secreted by the adrenal cortex exert their inhibitory action both on the brain and on the pituitary gland (Figures 3 and 4). The PVN of the hypothalamus contain the final common pathway neurons that mediate the neural control of pituitary ACTH synthesis and release (see **Secretagogue**). The PVN receive stimulatory and inhibitory neural inputs and an important projection from the suprachiasmatic nuclei (SCN), the key circadian oscillator in brain. PVN drive is mediated by stress neurohormones, corticotropin releasing factor-41 (CRF-41) and arginine vasopressin (AVP), which are released into hypophyseal portal vessel blood. ACTH is released into the systemic circulation and stimulates adrenal corticosteroid synthesis and release. In keeping with revised standard nomenclature, CRF-41 will be abbreviated to CRH (corticotropin-releasing hormone).

The release of ACTH is pulsatile in humans and is cleared rapidly from the blood by both metabolic degradation and distribution into several body

Figure 3 Block diagram of the hypothalamic-pituitary-adrenal glucocorticoid control system. Abbreviations: if, input forcing of adrenal by ACTH; pf, parametric forcing of adrenal (hypertrophic effect) caused by ACTH over a longer time period. The parametric effect of changes in adrenal blood flow is also indicated. The designators 0, + and 0, - indicate that signals in pathways are restricted in values (e.g., there are no negative masses or frequencies, and removal processes or inhibitors are negative in effects). From Yates, F. E. and Maran, J. W. (1975). In: Knobil, E. & Sawyer, W. H. (eds.) *Handbook of physiology* (pp. 367–404). Washington, D.C.: American Physiological Society, with permission.

compartments. The glucocorticoids are bound rapidly by albumin and a specific corticosteroid-binding protein, transcortin, and are metabolized by several organs, especially the liver and kidney (Figure 3). Only unbound (free) glucocorticoids inhibit ACTH release, and therefore the degree of glucocorticoid binding and metabolism, as well as the magnitude of adrenal secretion (Figure 3), determines the strength of the negative feedback signal. The HPA feedback system might also be influenced by a CRH-binding protein in plasma (first discovered by Orth and Mount in 1987). The physiological role of the CRH-binding (glyco) protein, which is synthesized in the liver, awaits to be determined – in humans, CRH-binding protein concentrations in plasma increase during the third trimester of pregnancy (see **Corticotropin Releasing Factor-Binding Protein**).

Interaction between Negative Feedback and Circadian Rhythm in the HPA System

The circadian rhythm of ACTH and (the consequent) glucocorticoid secretion, which has a peak at the end

and a nadir at the beginning of the sleep phase, is driven by a neural mechanism mediated mainly by the stress neurohormones. The twofold increase in the ACTH signal between the nadir and the peak of the circadian rhythm in the rat results in a ninefold increase in corticosterone due to an increase in the responsiveness of the adrenal cortex.

In the unstressed state, the HPA system operates in an approximately linear domain with all the loop variables (Figure 3) showing circadian periodicity. Ultradian rhythms in plasma cortisol concentration, independent of ACTH concentration, occur in humans and rhesus monkeys, in which they are highly synchronized between animals with a predominant periodicity of 85–90 min.

The circadian rhythm of ACTH secretion is driven by the SCN. In addition to the diurnal rhythm of corticosterone, the SCN are involved in other key rhythms in the body, such as the sleep–wake cycle, motor activity, thermoregulation, pineal *N*-acetyl transferase activity, and the regular occurrence of ovulation. If any one of these functions is abnormal, then there is a high probability that the others will

Figure 4 Schematic diagram of the elements involved in glucocorticoid negative feedback. The paraventricular nuclei (PVN) contain the main stress (final common pathway neurons) secreting both CRH and AVP. The negative feedback action of cortisol (corticosterone in rodents) is exerted mainly on the PVN and the pituitary corticotropes. However, long-term effects mediated through the hippocampus (Hipp) and amygdala (not shown) cannot be excluded. There are several possible indirect connections between the hippocampus and PVN. Neural control of ACTH secretion may also be mediated by a corticotropin inhibitory peptide, atrial natriuretic peptide (ANP). The inset shows the important inhibitory action of cortisol on the immune defense system (IDS). The IDS produces cytokines (CYT), which act on the brain to stimulate ACTH secretion. Cytokine secretion is inhibited by the negative feedback effect of glucocorticoids.

also be abnormal. The corticosterone rhythm is especially sensitive in that even partial lesions of the SCN, which have no effect on any of the other circadian functions, do disrupt the adrenal rhythm.

The SCN receive afferent projections from (1) the retina (direct as well as indirect after a relay in the ventral lateral geniculate nucleus), (2) the 5-hydroxytryptamine (5-HT) raphe neurons, and (3) the hippocampus by way of the medial corticohypothalamic tract. Each of these inputs to the SCN is likely to affect the periodicity of the pacemaker: the retinal input affects the time of the light–dark cycle; the hippocampal input may be related to the sleep–wake cycle; the raphe input may be related to paradoxical sleep. The raphe input also plays a major role in determining the amplitude of diurnal ACTH oscillations.

Although the central action of glucocorticoids is mainly on the PVN, the 5-HT neurons of the dorsal raphe nuclei, which project to the SCN, have high concentrations of glucocorticoid receptors. The SCN have direct projections to the PVN and may also affect PVN function by way of their projections to the subparaventricular zone. While circadian rhythmicity of the HPA is modulated by glucocorticoids and other factors, the intrinsic rhythmicity of the SCN circadian pacemaker is primarily under genetic control (see **Circadian Rhythms, Genetics** of).

Corticosteroid Feedback on the Hypothalamus and Pituitary Gland: Phase Differences

The seminal modeling studies of Eugene Yates and associates suggested that corticosteroid negative feedback on ACTH release occurs in three phases: a fast and immediate rate-sensitive phase of about 30 min, followed by a level-sensitive phase that occurs 2–3 h after the start of corticosteroid administration, followed by a long-term chronic phase. Fink and associates investigated the effect of corticosteroids on the release of stress neurohormones into hypophyseal portal blood (see **Neuroendocrine Systems**) in the intermediate and chronic phase. They found that adrenalectomy induced a three- to fourfold increase in the release of both CRH and AVP into hypophyseal portal blood. Administration of the synthetic glucocorticoid dexamethasone 2.5 h before portal blood collection significantly reduced the release of AVP, but not CRH (**Figure 5**), and also blocked the ACTH response to CRH (**Figure 6**). These findings suggest that intermediate-delayed (2–3 h) glucocorticoid feedback is mediated by the blockade of pituitary responsiveness to CRH and a reduction in AVP output into hypophyseal portal blood. That is, in this situation AVP is the regulatory or signaling neurohormone,

Figure 5 The delayed negative feedback action of glucocorticoid in adult female Wistar rats anesthetized with sodium pentobarbitone. ACTH was measured in plasma taken immediately before sectioning of the pituitary stalk for the collection of hypophyseal portal vessel blood. Adrenalectomy (ADX) resulted in a fourfold increase in ACTH concentration and a similar increase in the output of AVP and CRH release relative to that in intact, untreated animals (control). The administration of dexamethasone (DEXA) significantly reduced the levels of ACTH and AVP, but not CRH. Modified from Fink, G., Robinson, I. C. A. F. and Tannahill, L. A. (1988). Effects of adrenalectomy and glucocorticoids on the peptides, CRF-41, AVP and oxytocin in rat hypophyseal portal blood. *Journal of Physiology* **401**, 329–345, with permission of the authors and Cambridge University Press.

whereas CRH is the permissive neurohormone. In contrast, studies on the long-term effects of corticosterone administered by a subcutaneous pellet suggested that long-term negative glucocorticoid feedback is due to a decreased release of CRH, as well as AVP, into portal blood. That is, both stress neurohormones are sensitive to the long-term effects of corticosteroids.

These findings agree broadly with those of Plotsky and associates, which showed that pharmacological adrenalectomy with metyrapone and aminoglutethimide (which block glucocorticoid biosynthesis) resulted in a significant increase in the release of both CRH and AVP into hypophyseal portal blood. The intravenous infusion of corticosterone inhibited nitroprusside-evoked CRH release into portal blood, but had no effect on AVP release.

Data in the rat are complemented by those obtained in the sheep. Thus, the concentrations of CRH and AVP in hypophyseal portal blood collected from conscious sheep were (1) similar to those in the rat, (2) increased by volume depletion, fear-associated audiovisual stimuli, and insulin-induced hypoglycemia, and (3) inhibited by dexamethasone.

Figure 6 Mean ($\pm$ SEM, $n = 5$) percentage increase over the basal concentration of ACTH after the injection of saline, 0.1 µg CRH, or 3 µg CRH. Female Wistar rats that had been adrenalectomized 3 weeks earlier were treated with either saline or dexamethasone 3 h before injection of CRH. Note that dexamethasone blocked the ACTH response to 3.0 µg of CRH. From Fink, G., Robinson, I. C. A. F. and Tannahill, L. A. (1988). Effects of adrenalectomy and glucocorticoids on the peptides, CRF-41, AVP and oxytocin in rat hypophyseal portal blood. *Journal of Physiology* **401**, 329–345, with permission of the authors and Cambridge University Press.

Glucocorticoid Feedback Effects on Stress Neurohormone Biosynthesis

Glucocorticoids have potent inhibitory effects on CRH biosynthesis as well as release. Thus, adrenalectomy is followed by a significant increase in CRH mRNA levels in the parvocellular PVN, and this increase can be reduced by either corticosterone or dexamethasone. As assessed by CRH-intron *in situ* hybridization, the stimulation of CRH gene transcription can be detected as early as 15 to 30 min after the injection of the glucocorticoid synthesis inhibitor metyrapone. This increase in CRH gene transcription in the PVN was associated with a coincident increase in *c-fos* mRNA in the PVN. An increase in the levels of CRH mRNA in the PVN after metyrapone injection was delayed by about 60 min, possibly a function of the high resting levels of CRH mRNA and the time taken to assemble mRNA from the CRH primary transcript.

The effects of corticosterone and dexamethasone are dose dependent and can be demonstrated by systemic administration of the steroid, as well as by implantation of steroid pellets into the brain. This effect of glucocorticoids is cell specific in that the glucocorticoid-induced decrease in CRH mRNA was localized to the dorsomedial parvocellular neurons of the PVN, the major source of CRH fiber projections to the median eminence. In contrast, glucocorticoid increased the levels of CRH mRNA in parvocellular

neurons that project to the brain stem and the spinal cord. The implantation of dexamethasone micropellets in cerebral cortex, dorsal hippocampus, ventral subiculum, lateral septum, or amygdala had no effect on CRH mRNA levels in the PVN.

The molecular mechanism by which glucocorticoids regulate CRH gene expression remains unclear. Recent data show that the repressor isoform of cAMP response element modulator (CREM) is involved in CRH gene regulation, and that, *in vivo*, stress-induced glucocorticoids do not limit CRH gene transcription, in spite of the fact that the CRH promoter has a glucocorticoid receptor response element. The inhibitory effect of glucocorticoids on CRH gene transcription may be mediated, at least in part, by GABAergic, glutamatergic, and monoaminergic projections to the PVN from the forebrain and hindbrain limbic system.

The concentration of AVP mRNA in the dorso-medial parvocellular neurons of the PVN paralleled those of CRH mRNA, that is, levels increased after adrenalectomy and decreased after treatment with glucocorticoids. Corticosterone treatment also produced a modest reduction in the levels of enkephalin mRNA in all four regions of the PVN, but glucocorticoid manipulation had no significant effect on the PVN concentrations of the mRNAs for angiotensin, cholecystokinin, preprotachykinin, and tyrosine hydroxylase. There is, therefore, a close correlation between the synthesis and the release of CRH and AVP. Whether this means that synthesis and release are mechanistically coupled is not established.

Data on the release and synthesis of stress neurohormones suggest that even though corticosteroid receptors are present in high concentration in parts of the brain remote from the hypothalamus, including the hippocampus, amygdala, and the monoaminergic nuclei of the hindbrain, central inhibition of CRH and AVP synthesis and release may be due in large part to corticosteroid action mainly at the level of the PVN. Although a role for mineralocorticoid receptors cannot be excluded, glucocorticoid receptors predominate.

Role of Atrial Natriuretic Peptide in Glucocorticoid Inhibition

Fink and associates showed that atrial natriuretic peptide (ANP) is released into hypophyseal portal blood and, by immunoneutralization, that ANP is possibly an inhibitor of ACTH release. This suggests that the glucocorticoid inhibition of ACTH release may be mediated in part by ANP. A consensus sequence for the glucocorticoid response element is present in the second intron of the ANP gene, and ANP gene expression in and ANP release from cardiac cells are increased significantly by glucocorticoids.

A pathophysiological role for ANP is suggested by multiple trauma and septic shock in humans, where, paradoxically, plasma ACTH concentrations are decreased but plasma cortisol concentrations are increased. These results raise the possibility that under conditions of extreme stress, increased levels of ANP inhibit ACTH release while cortisol secretion is stimulated by a direct action of endothelin-1 on the adrenal gland. ANP inhibition of ACTH release might also explain the dissociation between plasma ACTH and CRH in patients who have undergone cardiac surgery or sustained myocardial infarction. Dissociation between plasma concentrations of ACTH and CRH under extreme, and especially cardiopulmonary, stress is relevant to allostatic override of the normal glucocorticoid negative feedback system.

On the basis of all the present *in vivo* and *in vitro* data, Engler and colleagues conclude that studies with ANP have so far provided the most compelling evidence that a neuropeptide may inhibit ACTH release.

Role of Hippocampus and Amygdala in Glucocorticoid Negative Feedback

It has long been assumed that the hippocampus and the amygdala, major components of the forebrain limbic system, play a key role in the stress response. The forebrain limbic system, together with the thalamus and neocortex and brain stem structures, form an analyzer-integrator system involved in neuroendocrine control. The hypothalamus can be considered an intermediate relay station in the reciprocal circuits between the limbic forebrain and brain stem structures, receiving inputs from both. The forebrain limbic system is thought to be involved in stressors that require analysis by higher brain structures (processive stressors), whereas direct brain stem projections to the PVN subserve stressors that pose an immediate physiological threat (systemic stressors).

Projections to the PVN from the hippocampus are mainly multisynaptic, involving (1) the hippocampal fimbria-fornix system involving the lateral septum, bed nucleus of the stria terminalis (BNST), and anterior hypothalamus, which all project to the parvocellular PVN, and (2) the medial corticohypothalamic tract from the anteroventral subiculum to the ventromedial, arcuate, and suprachiasmatic nuclei of the hypothalamus. The PVN also receive direct projections from the amygdala as well as projections that relay in the BNST.

Many, but not all, studies in which HPA activity was assessed by the assay of corticosterone and, less frequently, ACTH suggest that the hippocampus inhibits HPA activity. Hippocampal inhibition of the

HPA appears to be due mainly to corticosteroid negative feedback inhibition, although there is also evidence that the hippocampus may exert an inhibitory tone on the HPA independently of corticosteroid feedback. However, the hippocampus is neither the only site nor necessarily the major site of corticosteroid negative feedback, since removal of its input to the hypothalamus reduces, but does not abolish, the efficacy of corticosteroid inhibition. Thus, for example, (1) although electrical stimulation of the PVN resulted in a two- to threefold increase in CRH release into hypophyseal portal blood, stimulation of the hippocampus had no effect on the release of CRH, AVP, or oxytocin; (2) transection of the fornix, the major hippocampal-hypothalamic connection, had no significant effect on either basal or stress (nitroprusside-induced hypotension) evoked CRH release into hypophyseal portal blood; and (3) implantation of dexamethasone pellets in hippocampus had no effect on CRH synthesis in the PVN. Nevertheless, fornix section did elevate AVP concentrations in portal blood and blocked corticosterone reduction of elevated CRH, but not AVP, levels in portal blood during hypotensive stress.

Further evidence that the hippocampus normally moderates the synthesis of stress neurohormones is suggested by the finding that lateral fimbria-fornix lesions increased CRH mRNA and AVP mRNA in medial parvocellular PVN, and also plasma ACTH concentrations.

Feldman and Weidenfeld showed that, in freely moving male rats, photic and acoustic stimuli depleted the CRH content of the median eminence with a concomitant increase in plasma ACTH and corticosterone levels. This photic/acoustic activation of the HPA was inhibited by the systemic administration of dexamethasone. HPA inhibition by dexamethasone was in turn inhibited by hippocampal implants of glucocorticoid and, to a lesser extent, mineralocorticoid receptor antagonists. These results suggest that in conscious animals the hippocampus does play a role in corticosteroid feedback inhibition of stress-induced ACTH release.

Herman and associates have underscored the role of the BNST as a nucleus that integrates or processes hippocampal and amygdaloid modulation of the HPA. This hypothesis is based, first, on the anatomical connections of the BNST in that the nucleus receives rich projections from the amygdala and hippocampus and projects to the parvocellular PVN. Second, lesion of the anterior BNST resulted in a 30% decrease in CRH mRNA levels in the PVN, whereas lesion of the posterior BNST resulted in a 13% increase in the level of CRH mRNA in the PVN. On the basis of these data, Herman and colleagues

inferred that the anterior BNST integrates excitatory inputs mainly from the amygdala, whereas the posterior BNST integrates inhibitory inputs mainly from the hippocampus.

In summary, the hippocampus plays an important role in moderating the HPA both by mediating corticosteroid negative feedback and by exerting an endogenous inhibitory tone on the HPA. Corticosteroid negative feedback is also exerted directly on the PVN and the pituitary gland. The hippocampus is a heterogeneous structure; thus, for example, Dunn and Orr found that electrical stimulation of the CA1 region increased corticosterone levels, whereas stimulation of the CA3, dentate, and subiculum decreased plasma corticosterone concentrations. This heterogeneity will need to be considered in the design of further studies on the role of the hippocampus in negative feedback control of the HPA.

Glucocorticoid Negative Feedback at the Pituitary Level

As well as exerting a central effect, corticosteroids inhibit ACTH synthesis and release by an action at the level of the anterior pituitary gland. As in brain, the inhibitory action of corticosteroids on pituitary corticotropes is mediated by glucocorticoid (type II) receptors.

Studies on dispersed pituitary cells with inhibitors of mRNA and protein synthesis have shown that both the rapid and delayed glucocorticoid inhibition of ACTH release depends upon mRNA and protein synthesis. Glucocorticoids also exert potent inhibitory effects on the expression of the ACTH precursor proopiomelanocortin (POMC) in the anterior lobe of the pituitary gland. In male Sprague-Dawley rats, transcription assays showed that dexamethasone inhibited POMC gene transcription by 10-fold within 30 min of a single injection of the glucocorticoid. Inhibition of POMC transcription was paralleled by a dramatic fall in plasma ACTH concentrations. The same study showed that CRH stimulated POMC transcription by nearly twofold within 15 min, which coincided with a massive increase in ACTH release. The action of dexamethasone is cell specific in that the steroid had no effect on the transcription rate of POMC in primary cultures of neurointermediate lobe cells.

Studies in transgenic mice showed that no more than 769 base pairs of the rat POMC promoter are required for cell-specific expression and glucocorticoid inhibition of the POMC gene in the anterior pituitary gland. A good deal is known about the glucocorticoid response elements in the POMC promoter and the transcription factors involved in POMC

expression, but the precise molecular mechanism of glucocorticoid inhibition of POMC transcription remains to be elucidated.

In addition to a direct action on POMC gene expression, which determines the amount of ACTH available for release, glucocorticoids inhibit ACTH release by a mechanism mediated by adenylate cyclase (see Adenylyl Cyclases and Stress Response).

Possible Role of 11 β -Hydroxysteroid Dehydrogenase

Two types of 11 β -hydroxysteroid dehydrogenase play a pivotal role in glucocorticoid synthesis and metabolism. This enzyme is involved in glucocorticoid negative feedback (see 11 β -Hydroxysteroid Dehydrogenases).

Functional Importance of Glucocorticoid Negative Feedback

Glucocorticoid feedback inhibition of ACTH release protects the organism against the deleterious effects of hypercortisolemia (excessive concentrations of cortisol in blood). Whether due to endocrine disorders, such as Cushing's syndrome, or other causes such as trauma or chronic stress, hypercortisolemia is associated with at least three major deleterious effects. First, it suppresses the immune-inflammatory defense system and so incapacitates the animal's ability to respond to infection by pathogenic microorganisms or to chemical or physical insult. Second, persistent hypercortisolemia has major adverse effects on intermediary metabolism, resulting eventually in all the features of Cushing's syndrome, that is, android obesity, diabetes mellitus, hyperlipidemia, hypertension, and osteoporosis. Third, hypercortisolemia and/or stress are associated with reduction in hippocampal volume (atrophy) in several neuropsychiatric disorders, such as depression and posttraumatic stress disorder, as well as in Cushing's syndrome. In all three disorders, the hippocampal atrophy is associated with explicit memory deficits.

Clinical Manifestations of Disordered Glucocorticoid Feedback Regulation of the HPA System

No attempt is made here to give a detailed account of the clinical effects of disruption of feedback control within the HPA system. Rather, this section considers two clinical examples that underscore the principles of negative feedback and illustrate the consequences of disruption of normal HPA feedback control.

The first example is of enzyme defect in the adrenal cortex that results in the absence or deficiency of the afferent glucocorticoid signal of the HPA negative feedback system, whereas the second is probably due to an alteration in the central set point of the negative feedback control system.

Congenital Adrenal Hyperplasia: Failure of Glucocorticoid Negative Feedback

There are several types of inherited enzymatic defects in cortisol synthesis known to result in congenital adrenal hyperplasia (CAH), also known as the adrenogenital syndrome. By far the most common form is due to a deficiency of P450_{c₂₁} (21-hydroxylase; see Figure 7), which leads to a deficiency in cortisol biosynthesis. Excessive androgen secretion results from a failure of glucocorticoid negative feedback and consequent, uncontrolled, high ACTH secretion. Excessive androgen levels may lead to virilization of females *in utero*. About two-thirds of patients also have mineralocorticoid deficiency, resulting in salt wasting. If not obvious during the neonatal period, androgen excess may appear in early infancy, resulting in sexual precocity in boys and clitoral enlargement and pubic hair growth in girls. Excess androgen accelerates linear growth and epiphyseal closure, leading ultimately to diminished adult height. In adult women with untreated CAH, reproductive function is impaired due to (1) the disturbance of normal menstrual cycles as a consequence of the high plasma progesterone and androgen concentrations and (2) labial fusion, which prevents successful coitus. The former can be corrected by glucocorticoid replacement therapy, whereas the latter can be treated surgically.

The P450_{c₂₁} deficiency is transmitted as a single gene autosomal recessive trait linked to the major histocompatibility complex locus on the short arm of chromosome 6. An allelic variable of classical 21-hydroxylase deficiency results in a late-onset type, which frequently presents with clinical features similar to those of polycystic ovarian disease.

Deficiency of P450_{c₁₁} (11 β -hydroxylase) is a much less common cause of CAH. As in the case of P450_{c₂₁} deficiency, it is transmitted as an autosomal recessive disorder but is not linked to the HLA locus. As in the case of P450_{c₂₁} deficiency, a deficiency in P450_{c₁₁} results in impaired glucocorticoid feedback and a consequent hypersecretion of ACTH and adrenal androgens. The condition is treated with glucocorticoid replacement therapy.

Much more rare forms of CAH are produced by deficiencies of 17 α -hydroxylase and 3 β -hydroxysteroid dehydrogenase, which result in defective adrenal androgen, as well as glucocorticoid secretion.

Figure 7 A diagrammatic representation of the steroid biosynthetic pathways in humans. I to VI correspond to numbers for specific biosynthetic defects that result in congenital hyperplasia. P450_{SCC}, cholesterol side chain cleavage; 3 β -HSD, 3 β -hydroxysteroid dehydrogenase/ Δ^4 - Δ^5 -isomerase; P450_{c21}, 21-hydroxylase; 17 β -HSD, 17 α -hydroxysteroid oxidoreductase; P450_{c11} catalyzes 11 β -hydroxylation, as well as 18-hydroxylation and 18-oxidation; P450_{c17} catalyzes 17-hydroxylation and 17,20-lyase activity. Hypercortisolemia in Major Depression: Possibly due to an Altered Set Point in Glucocorticoid Negative Feedback

Major depressive disorder is characterized by a significant increase in plasma cortisol concentrations (hypercortisolemia), which is most prominent at the nadir of the circadian rhythm around midnight. It was first thought that hypercortisolemia and resistance to the suppression of endogenous cortisol secretion by dexamethasone were specific features of major depression, which led to the hope that the dexamethasone suppression test could be used as a specific biological marker of depression. However, extensive studies have shown that hypercortisolemia and resistance to dexamethasone suppression are also associated with other types of psychoses, such as schizoaffective disorder and organic dementia, including Alzheimer's disease.

As shown by Goodwin and associates, hypercortisolemia in major depression is associated with a threefold increase in the mean plasma concentration of β -endorphin. In fact, resistance of β -endorphin to dexamethasone suppression appears to be a more robust marker of major depression than cortisol. Thus, in a study by Young and associates of 73 patients

with major depressive disorder, 39 (53%) showed β -endorphin nonsuppression to dexamethasone, while only 8 patients (11%) showed cortisol non-suppression. These findings suggest that hypercortisolemia in major depression is due to a resistance of the brain-pituitary-ACTH module to glucocorticoid negative feedback, that is, an elevation of the set point for glucocorticoid feedback. The precise mechanism remains to be determined, but decreased responsiveness of the limbic system, PVN, and/or pituitary gland to glucocorticoid negative feedback is a likely explanation. Reduced responsiveness of the PVN could be caused by transynaptic changes triggered by changes in function of the limbic system and frontal cortex. Because the serotonergic raphe neurons determine the amplitude of the circadian excursions of plasma ACTH and corticosterone, it is also conceivable that hypercortisolemia reflects dysregulation of serotonergic function, which seems to occur in major depression.

Allostasis and Allostatic Load

Allostasis and allostatic load are mentioned here to clarify the link between homeostasis and allostasis.

The latter refers to maintenance of stability through change or adaptation and is illustrated by the increase in blood pressure on waking or sex to cope with extra circulatory demands. In normal subjects, the increased blood pressure required to match increase in load does not necessarily reflect all but a transitory override of blood pressure control mechanisms involving baroreceptors (pressure receptors in the carotid sinus) and chemoreceptors (chemical sensors in the carotid body). Rather, there is a shift or adaptation in set point of the blood pressure control system so that it maintains mean arterial blood pressure within narrow limits around the new set point commensurate with the new load. Simply put, this is the same as altering the set point of a thermostat in a room to increase or decrease the mean ambient temperature – the set point has been changed, but the control mechanisms remain the same. The same principle may be applied to the control of plasma cortisol or adrenaline concentrations. The ability to alter the set point of one or more feedback control systems is termed regulation. In the case of the HPA and systemic blood pressure, set point regulation is located within the CNS. The elements that change the controlled variable (e.g., blood pressure, cortisol, adrenaline) toward the new set point are the control mechanisms.

Allostatic load was first introduced and defined by McEwen and Stellar (McEwen 2001) “as the cost of chronic exposure to fluctuating or heightened neural or neuroendocrine response resulting from repeated or chronic environmental challenge that an individual reacts to as being particularly stressful.” That is, allostatic load reflects the hidden cost of chronic stresses to the body that act as a predisposing factor for the adverse effects of acute, stressful life events.

Conclusion

The HPA system, together with the sympathetic-medullary system, plays a pivotal role in the neuroendocrine response to stress. Homeostasis within the HPA is maintained by a precise negative feedback system by which the adrenal glucocorticoids (the afferent inhibitory signal), cortisol in humans or corticosterone in rodents, moderate ACTH synthesis and release (efferent output signal). Allostasis – that is, change in HPA activity to cope with increased stress load – is brought about by change in feedback set point. The major sites of negative feedback are the PVN, where glucocorticoids inhibit CRH and AVP synthesis and release, and the pituitary gland, where they block the ACTH response to CRH and inhibit POMC/ACTH synthesis. The limbic system of the brain, especially the hippocampus and amygdala,

plays an important role in glucocorticoid negative feedback control.

Disruption of the HPA negative feedback system has serious deleterious effects, a point illustrated by the congenital adrenogenital syndrome and hypercortisolemia associated with serious mental illnesses. The adrenogenital syndrome, due to defective or absent cortisol secretion (loss of the afferent feedback signal) consequent on a congenital enzyme defect in the adrenal cortex, results in massive uncontrolled pituitary ACTH release. The latter induces excessive androgen production that in turn causes precocious puberty in males and masculinization of females. Hypercortisolemia, a prominent feature of major depressive disorder and other psychoses and organic dementias, is probably due to elevation of the set point of the HPA negative feedback system. Elucidation of the precise cause of this change in feedback set point may provide insight into the central disorder in depression. Hypercortisolemia may exert adverse effects by (1) inhibiting immune-inflammatory defense mechanisms, (2) disrupting intermediary metabolism, (3) inducing effects akin to Cushing’s syndrome that lead to obesity, diabetes type II, and osteoporosis, and (4) compromising hippocampal structure, neurogenesis, and function that might lead to cognitive impairment.

Interactions with the Stress Circuitry
Effects of Stress on Food Intake
Effects of Feeding (or Fasting) on Stress Responses
Concluding Remarks

Glossary

<i>Anorexigenic</i>	Inhibiting food intake (e.g., POMC (α -MSH), CART, leptin).
<i>Arcuate nucleus</i>	A collection of neurons (nerve cells) in the hypothalamus.
<i>Hypothalamus</i>	Region of the brain linking the nervous system to the endocrine system by synthesizing and secreting neurohormones and neuropeptides. The hypothalamus is also the area of the brain that controls hunger and thirst, body temperature, and circadian cycles.
<i>Orexigenic</i>	Stimulating food intake (e.g., AgRP, NPY, ghrelin).

Neural Circuitry Involved in Food Intake

Food intake involves several aspects of different behaviors, such as hunting for food and decision making. The complexity of feeding behavior is reflected in the number of brain areas involved; several nuclei in the caudal brain stem, hypothalamus, and the corticolimbic area are part of the feeding circuitry. Despite the large number of brain areas involved in feeding behavior, the hypothalamus is regarded as the main center for regulation of homeostatic feeding in the brain. Within the hypothalamus, the arcuate nucleus is central to the regulation of food intake. The arcuate nucleus contains at least two distinct groups of neurons controlling food intake: neurons that contain the orexigenic neuropeptides agouti-related protein (AgRP) and neuropeptide Y (NPY) and neurons that contain the anorexigenic neuropeptides pro-opiomelanocortin (POMC) and cocaine- and amphetamine-regulated transcript (CART). These arcuate neurons contain different receptors of hormones that are secreted in the periphery by adipocytes, the pancreas, and the gut in response to nutrients passing or being

stored. Leptin, for example, is secreted by adipocytes, reflecting the amount of fat stores in the body. When the body becomes fat, leptin will silence orexigenic neurons and trigger anorexigenic neurons in the arcuate nucleus to secrete α -melanocyte-stimulating hormone (α -MSH) (derived from POMC) and CART to decrease food intake. In contrast to leptin, the hormone ghrelin, which is released from the (empty) stomach and which has been associated with the anticipation of meals, activates NPY/AgRP neurons and inhibits POMC/CART neurons in the arcuate nucleus. The neurons of the arcuate nucleus project to several nuclei within the hypothalamus, such as the paraventricular (PVN) and the lateral hypothalamic (LHA) nuclei, which also receive and send information from and to the caudal brain stem and corticolimbic areas. In addition to the anorexigenic and orexigenic neuropeptides in the arcuate nucleus, within the PVN corticotropin-releasing hormone (CRH) and within the LHA melanin-concentrating hormone and orexin(s) are peptides also involved in food intake regulation. Within the brain stem, groups of catecholamine cell groups are localized that project to the hypothalamus and are important for the regulation of feeding behavior, for example, in response to a glucoprivation. In the brain stem, integration of signals from the periphery (such as cholecystokinin [CCK]) takes place, carrying information on gastrointestinal distention and presence of meals in the gastrointestinal tract and signals from the hypothalamus indicating long-term nutritional status. For instance, leptin and α -MSH affect meal size, probably by determining the sensitivity for CCK at the level of the brain stem, which is released when fat-containing foods reach the duodenum. Furthermore, within the corticolimbic area, the amygdala and nucleus accumbens are implicated in the evaluation of taste and rewarding aspects of food. Taken together, this complex neural circuitry holds many brain areas, in which neuropeptides and neurotransmitters convey information important for the regulation of feeding behavior.

The brain, however, does not function on its own. To maintain a stable body weight, food intake needs to be tuned to the needs of the peripheral body. This means that when fat stores are increasing or depleting, satiety or hunger factors (e.g., hormones) are produced by different organs to change feeding behavior. For example, leptin that is secreted from adipose tissue acts on its receptor in the arcuate nucleus to decrease food intake. In addition, glucocorticoids

secreted by adrenals in response to fasting act as factors to adjust feeding behavior.

Interactions with the Stress Circuitry

During stress, several neuropeptides and hormones are affected that are part of the previously described neural circuitry involved in feeding behavior. CRH in the PVN plays an initiating role in hypothalamic-pituitary-adrenocortical (HPA) axis activity and is increased with acute stress and decreased with chronic stress (through feedback effects of released glucocorticoids). In addition, acute stress increases NPY mRNA in the arcuate nucleus. In the amygdala, which is also part of processing taste information, NPY mRNA will decrease whereas CRH mRNA will increase after a stressful event. Thus, during stress, depending on the anatomical site, anorexigenic (CRH) as well as orexigenic (NPY) signaling is increased. This might result in conflicting food intake signals. Interestingly, some eat more while others eat less following stressful experiences. The individual sensitivity and reactivity in these different neural circuits may underlie the response of food intake to a stressful situation. It has also been shown that NPY induces changes in the daily rhythm of circulating corticosterone (which shows a rhythm over the day-night cycle) when rats' food intake is restricted. Interestingly, AgRP, but not NPY, mRNA levels are reduced following a stressful event. Thus, although both orexigenic neuropeptides are colocalized in the arcuate nucleus and their expression appears similarly affected following fasting, their expression is differently regulated following a stressor. Also, α -MSH interacts with the stress circuitry; central administration of α -MSH stimulates grooming and the release of ACTH and corticosterone in rats, and this activation is further increased in stressed rats.

Another overlapping system for food intake and stress responsivity is the catecholaminergic pathway between the brain stem and the hypothalamus, which is involved in feeding behavior as well as in stress responsivity. Physiological evidence that these systems indeed interact is provided by data showing effects of stress on food intake and vice versa.

Effects of Stress on Food Intake

Human studies showed that the psychophysiological response to stress is related to greater food consumption. Stress is the main trigger for obese patients to start binge eating. Moreover, people that release more cortisol due to a stressor are consuming more calories and eat significantly more sweet foods across days. Stress eaters gain more weight and are at greater risk

for cardiovascular disease and type II diabetes. In Cushing's disease as well as in patients treated with corticosteroids for longer periods, a typical visceral form of obesity is induced. Generally, adrenal insufficiency is accompanied by reduced food intake and body weight. Removal of the adrenal glands in rodents results in reduced food intake and body weight, which demonstrates that corticosteroids are essential for maintaining a normal body weight. More severe traumatic environmental stressors (e.g., the loss of a spouse) can have an opposite effect, decreasing food intake and fat stores. Stress is also thought to play a central role in anorexia nervosa. The neurodevelopmental model of anorexia nervosa proposes that chronic stress in predisposed individuals results in (maladaptive) hyperactivity of the HPA axis, resulting in a loss of nutritional homeostasis. Other models, however, state that the principles of anorexia nervosa are starvation and physical activity, and that the consequential activation of the HPA axis is rewarding for the patient.

In animal models, the influence of stress (ranging from physical stress to social stress) on food intake has been studied extensively. The typical response of rodents to a wide range of stressors is to decrease food intake. Only in Syrian hamsters has it been shown that social stress increases food intake and fat stores. Most experiments studying effects of stress on food intake in rats and mice have been done using normal lab chow, which is balanced, healthy, and high in carbohydrates. In daily society, however, humans have choices, and often have easy access to cheap foods with high fat and sugar content. Providing rats with a greater choice of food results in different food intake responses when animals are subjected to a chronic stressor. Rats were given access to normal lab chow, lard, and a bottle of 1 M sugar water and were repeatedly restrained for 5 days, 3 h/day. Rats increased their intake of the more palatable items, lard and sugar, and consumed more of those as compared to the nonstressed animals.

Effects of Feeding (or Fasting) on Stress Responses

Although stress alters food intake regulation, the absence of food (fasting or starvation) is itself a stressful event. For instance, stress hormones and CRH (anorexigenic) are chronically increased in anorexia nervosa patients, which may contribute to the difficulty these patients experience in trying to reverse their illness. Stress from absence of food is, however, different from stressors such as restraint stress. Glucocorticoid receptors (GRs) in the hypothalamus are downregulated following chronic, repeated restraint,

thus decreasing negative feedback on CRH mRNA in the PVN. The decreased inhibition of CRH mRNA results in fewer anorexigenic effects of the PVN CRH during starvation. Furthermore, the ACTH response to stress is altered during fasting.

Not only does the absence of food change stress responsivity, but eating palatable (e.g., sugar- and fat-containing) food also changes the response to stress. Rats that voluntarily choose the percentage of lard in their diets (composing their own high-fat diet) have reduced HPA responses to restraint stress; however, when forced to eat a high-fat diet the response of the HPA axis to restraint is high or similar compared to rats that consume only chow. Some controversy exists regarding the stress responsivity when animals are eating a high-fat diet. Although the choice to eat fat seems important for the response to stress, rats that were force-fed a high-fat diet for a longer time did have decreased responses in activity and body temperature when socially stressed (social defeat).

Concluding Remarks

Stress clearly affects the neural circuitry regulating food intake at several levels. Some people react to stress by overeating, which contributes to the development of obesity, whereas others (e.g., anorexia nervosa patients) reduce their food intake. Differences in these coping strategies may originate in subtle differences between individuals in the neural circuitry underlying food intake and stress. A better insight into how the stress system interacts with the food intake circuitry, as well as into the mechanism underlying individual responsiveness to stress, is necessary to find new strategies to treat eating disorders such as obesity and anorexia nervosa. The type of diet also affects the stress response. Future research is needed to understand the mechanisms underlying how palatable food interacts with the neural circuitry of the stress response.

Glossary

Biophysical profile

A noninvasive test that identifies a compromised fetus. It integrates five parameters to determine the biophysical profile score: the nonstress test, ultrasound measurement of the amniotic fluid volume, observation of the presence or absence of fetal breathing movements, gross body movements, and fetal tone.

Cardiotocography (CTG)

A method of monitoring fetal heart rate using either an abdominal transducer or a probe on the fetal scalp; in addition, another transducer placed over the uterine fundus monitors uterine activity (contractions).

Cordocentesis

An invasive procedure that involves the aspiration of fetal blood from the umbilical cord under sonographic guidance for diagnostic (fetal-karyotyping) or therapeutic (blood/platelet-transfusion) purposes.

Doppler ultrasound

A noninvasive technique of blood-flow velocity measurement. The Doppler effect (named after Christian Andreas Doppler) is the apparent change in frequency and wavelength of a wave that is perceived by an observer moving relative to the source of the waves; the total Doppler effect may result from either the motion of the source or motion of the observer. For the velocity measurement of blood, ultrasound is transmitted into a vessel and the sound that is reflected from the blood is detected.

Preeclampsia

A pregnancy-specific multisystem disorder that is characterized by the development of hypertension of 140 mmHg or higher systolic or 90 mmHg or higher diastolic after 20 weeks of gestation in a woman with previously normal blood pressure and proteinuria of 0.3 g or more of protein in a 24-h urine collection (usually corresponds to 1+ or greater on a urine dipstick test).

Programming

The process whereby a stimulus or insult, when applied during a critical or sensitive period of development, results in a long-term or permanent effect on the structure or function of the organism.

Fetal Programming and Fetal Origins of Adult Disease

Experimental and clinical studies have highlighted the importance of the fetal environment in the subsequent growth and development of an individual. Indeed, a poor *in utero* environment elicited by maternal malnutrition or placental insufficiency may increase the susceptibility of the fetus to the later development of metabolic and cardiovascular disease. The fetal origins of adult disease hypothesis originated from the epidemiological research of Barker and colleagues, which demonstrated an association between low birth weight and cardiovascular disease, hypertension, insulin resistance, and dyslipidaemia later in life. In an attempt to explain this association, Hales and Barker proposed the thrifty phenotype hypothesis, according to which the fetus in a poor intrauterine environment maximizes the uptake and conservation of fuel resources by altering its metabolism. This alteration is adaptive in a deprived environment but maladaptive in an environment of plentiful resources.

The fetal programming response to environmental stressors, predictive adaptive response (PAR), however, is much broader than the one suggested by Barker and colleagues, extending well beyond energy use and conservation. PAR uses developmentally plastic processes to set a postnatal physiological and behavioral phenotype that the fetus predicts will offer an optimal chance for survival and reproduction during adulthood. The prediction of an adverse, deprived, risky, and hence stressful environment leads to adaptive changes in body size, body composition, organ size, neurohormonal activity, and many aspects of behavior. These predictive adjustments could be advantageous in a deprived environment but are maladaptive under abundant conditions.

Mediators of the Predictive Adaptive Response

The fetal adaptive response to stressors is mediated largely by the stress system. The hypothalamic-pituitary-adrenal (HPA) axis and the locus ceruleus–norepinephrine–sympathetic nervous system (LC-NE-SNS) and their mediators corticotropin releasing

hormone (CRH), arginine vasopressin (AVP), norepinephrine (NE), epinephrine (E), and cortisol are responsible for both the concurrent adaptive response to the stressor and for causing the long-term organizational changes in the brain and periphery that constitute the PAR. Indeed, CRH and cortisol have been shown to have strong activating and organizational effects.

Fetal Distress – Clinical Evaluation

In perinatology practice, the term fetal distress has been employed as the condition in which the fetal heart rate (FHR) pattern detected by cardiotocography (CTG) is abnormal during antepartum surveillance. The generation of reactive FHR patterns constitutes a complex process involving appropriately for gestational age mature brain-stem centres, normally functioning sympathetic and parasympathetic system, intact electrical pathways to conduct the contractile stimulus, appropriately functioning cardiomyocytes' neurohormone receptors, and normal cardiac partitioning and development.

CTG tracing patterns indicative of fetal hypoxemia and/or acidemia are characterized by fixed FHR baselines, loss of FHR variability, absence of accelerations and are described as 'non-reassuring'. Documentation of spontaneous late decelerations is associated with a significant risk of fetal compromise. CTG patterns can be influenced by constitutional and environmental parameters, such as fetal congenital abnormalities, fetal maturation (depending mainly on gestational age) and movements. Moreover, maternal emotional or physical stress and the use of medication can also generate abnormal FHR patterns. Fetuses exhibit restricted central nervous system maturation and therefore cerebral activity before 28 weeks of gestation. Thus, CTG monitoring before this gestational age usually demonstrates reduced variability and benign spontaneous decelerations. Fetal sleep cycles are frequent and longer monitoring is required to record reactivity.

In addition FHR patterns are correlated to the nature of the hypoxic insult. Acute hypoxemia generates abrupt and profound declines in FHR baseline and variability and fetal activity. Chronic hypoxemia is associated with a more gradual deterioration in these parameters and therefore may remain undiagnosed by CTG monitoring for days to weeks.

Numerous studies have assessed CTG sensitivity, specificity, and predictive values. Most of them have documented relatively high specificity (>90%) but much lower sensitivity (averaging 50%). Positive and negative predictive values are less than 50% and more than 90%, respectively, suggesting that

the non stress test (NTS) is better at excluding than diagnosing fetal compromise.

Despite extensive research, the association between a compromised fetus (invasively traceable by altered biochemical parameters) and a nonreassuring CTG pattern remains an unresolved issue. In addition, the correlation between an acute or chronic intrauterine adversity and the extent of fetal compromise caused by it, is not clearly defined regarding stressor's threshold level, intensity and duration required to impair fetal developmental, physiological and metabolic mechanisms. Furthermore, fetal capability to sustain a stressor is characterized by a wide range of adaptive mechanisms whose efficacy depends on gestational age and other only partially elucidated factors.

Fetal hypoxemia can be categorized, depending on the severity and duration of the *in utero* adversity, as acute or chronic. Acute hypoxemia as a stressor activates the fetal stress system. There is evidence from experimental studies that acute hypoxemia is associated with bradycardia and compensatory tachycardia, elevated blood pressure, reduced fetal breathing and reduced gross body movements, and increased cerebral blood flow, indicating cardiac redistribution. The fetal ovine HPA axis responds to acute hypoxemia with elevated arterial plasma concentrations of ACTH and cortisol. Furthermore, catecholamines and vasopressin concentrations are elevated in the hypoxic ovine fetus. In the sheep fetus during late gestation, episodes of acute stress induce endocrine responses that promote fetal adaptation and survival during the period of adversity.

Chronic hypoxemia is associated with the progressive return of fetal body movements, heart rate, and blood pressure to normal. However, cardiac output redistribution is maintained, as documented by increased cerebral blood flow. In fetal sheep, the partial compression of the umbilical cord for a period of three days causing a 30% reduction in umbilical blood flow can produce reversible mild fetal asphyxia, a transient increase in fetal plasma ACTH concentration, and a progressive and sustained increase in fetal plasma cortisol. Chronic hypoxemia is associated with increased NE concentrations. On the contrary epinephrine concentrations are restored to control levels during the course of hypoxemic period.

Hypoxia can activate a sequence of systemic, cellular, and metabolic responses, allowing tissue adaptation to the adverse effect of the lack of oxygen. Furthermore, hypoxia can induce altered gene expression with long-term detrimental outcome. The underlying molecular mechanisms that determine fetal development in response to hypoxia are not clearly defined, and it is suggested that placental gene upregulation is associated with the inflammatory response

after the hypoxic exposure. Hypoxia may cause placental insufficiency or may induce preeclampsia through an inflammatory response, leading to FGR or even to *in utero* demise. Additionally pro-inflammatory molecules, such as cytokines, are considered responsible for the systemic maternal inflammatory response observed in pregnancies complicated with preeclampsia.

Current research suggests that exposure to inflammatory stressors during the critical developmental windows may induce altered gene expression of the neuroendocrine-immune axis. Evidence of HPA axis and autonomic nervous system (ANS) activation during inflammation supports the hypothesis that inflammatory stress during fetal development induces the programming of both the neuroendocrine and immune systems, influencing vulnerability to disease development later in life. Moreover, both clinical and experimental studies suggest that low-grade systemic inflammation is present in the metabolic syndrome participating in the development of atherosclerosis and cardiovascular disease.

Fetal Growth Restriction (FGR)

Genetically predetermined fetal growth potential influenced by environmental parameters determines fetal growth and birth weight. These parameters can be physiological (fetal and maternal health and placental function), behavioral (maternal emotional stress), social (socioeconomic status, life-style and malnutrition), and ecological (starvation/famine). The interaction between genome and environment in the regulation of fetal growth and development constitutes a complex process. Intrauterine adversities challenge the growing fetus, forcing it to reallocate its energy resources between the adaptation to the challenge and growth in order to ensure survival, reproduction enhancement and genome preservation. Thus, FGR is the evolutionary result of adaptation to a suboptimal intrauterine milieu.

FGR occurs in approximately 5% of all human pregnancies and is associated with a substantially increased risk of perinatal mortality and long-term morbidity. The definition of FGR excludes small for gestational age (SGA) fetuses that are constitutionally small. Based on growth curves, growth-restricted fetuses are considered to be those with estimated weights below the 10th percentile for gestational age, below the 5th percentile for gestational age, or two standard deviations (<3%) below the mean for gestational age. Approximately 80% of fetuses with estimated weights below the 10th percentile for gestational age are constitutionally small (normal small), 15% are starved small due to placental insufficiency,

and 5% are abnormal small. The lower the percentile that defines SGA, the higher the likelihood of FGR.

FGR is further categorized as symmetric or asymmetric. Symmetric FGR is characterized by proportional reduction in growth velocity of both the fetal head circumference (HC) and abdominal circumference (AC), indicating a constitutionally small fetus. Symmetric FGR can also be indicative of *in utero* adversities such as chromosomal abnormalities, genetic syndromes, congenital infections, use of medication or teratogenic agents. Asymmetric FGR is characterized by a disproportional reduction in growth velocity of the fetal HC to AC and is mainly associated with placental insufficiency. However, body proportionality does not always specify the causes of FGR. Snijders et al. performed fetal blood karyotyping on 458 fetuses between 17 and 39 weeks gestation who had been referred for evaluation of intrauterine growth restriction (IUGR) and they demonstrated that the relative shortening of the femur can be found in both chromosomally normal and abnormal fetuses. In the same study, fetuses with triploidy had been found to have severe, early-onset, asymmetric FGR, whereas fetuses with chromosomal abnormalities other than triploidy were symmetrically growth retarded at <30 weeks. Chromosomally abnormal IUGR fetuses diagnosed after 30 weeks are usually asymmetrically growth restricted. The authors suggested that the asymmetry results from superimposed starvation due to placental insufficiency.

Placental insufficiency and fetal abnormalities (chromosomal, structural and congenital infections) are responsible for the majority of FGR cases in singleton pregnancies. According to histopathological studies, placental insufficiency is associated with abnormal trophoblast invasion and villous development that impairs placental vascular function, restricting nutrient and oxygen transfer to the fetus. The severity of placental insufficiency can be manifested in both maternal and fetal vascular compartments, (uterine and umbilical arteries respectively). The discrepancy between fetal growth demands and environmental conditions, mainly defined by placental vascular dysfunction, determines the severity of the compromised growth velocity that may manifest as FGR or even as fetal demise.

Clinical studies have documented the correlation between increased blood flow impedance in the uterine arteries and the subsequent development of preeclampsia, and FGR. Abnormal Doppler waveform in the uterine arteries is associated with a 70% chance of developing preeclampsia and an approximately 30% chance of developing growth restriction. In FGR pregnancies increased Doppler indices in the umbilical arteries are associated with fetal hypoxemia and

acidemia correlated to the severity of the impedance of the umbilical flow. Fetal cardiovascular adaptations to placental insufficiency result in the redistribution of cardiac output. As a consequence, there is an increase in the blood supply to the brain, myocardium, and the adrenal glands at the expense of the kidneys, gastrointestinal tract, and lower extremities. The aforementioned redistribution of cardiac output can be documented by the reduced impedance of the blood flow in the middle cerebral artery. Fetuses exhibiting blood flow redistribution are usually hypoxemic, while acidemia may still not be clinically apparent. Further deterioration of fetal circulatory status is manifested by cardiac decompensation due to the exhaustion of adaptive mechanisms to hypoxia, indicated by right heart failure and abnormal organ autoregulation.

Elegant studies investigating the metabolic status of growth-restricted fetuses by cordocentesis have documented fetal compromise by hypoxemia, hypercapnia, hyperlacticemia, and acidosis. Growth-restricted fetuses are deprived of glucose and amino acids and are hypertriglyceridemic. In addition, some of these fetuses are hypoinsulinemic and their degree of hypoinsulinemia is disproportional to the degree of hypoglycemia, suggesting pancreatic dysfunction. In growth-restricted fetuses, the plasma cortisol concentration is increased and inversely correlated to fetal hypoglycemia. There is evidence of a significant correlation between umbilical cord plasma CRH and both ACTH and cortisol concentrations, as well as a significant negative correlation between CRH and dehydroepiandrosterone sulfate (DHEAS) levels in the growth-restricted fetuses. The umbilical cord plasma CRH level is extremely elevated compared to that of normal fetuses.

Placental CRH synthesis and release, in contrast to hypothalamic CRH, appears to be stimulated by glucocorticoids. In pregnancies complicated by uteroplacental insufficiency, placental CRH production may be enhanced by increased fetal glucocorticoids. In turn, placental CRH may modulate fetal pituitary-adrenal steroidogenesis to favor increased cortisol secretion. Conditions of chronic stress may stimulate hypothalamic as well as placental CRH, modulating fetal pituitary-adrenal function and consequently fetal response to a compromised intrauterine environment.

In FGR fetuses there is delayed maturation of biophysical parameters is apparent in IUGR fetuses. Fetal behavioral responses to placental insufficiency can affect heart-rate control by delaying the physiological decline of the baseline heart rate and maturation of reactivity and by decreasing short- and long-term variability.

Diagnostic Approach to Fetal Growth Restriction

The best method to diagnose the growth-restricted fetus and determine its growth velocity is ultrasound evaluation. The diagnostic approach to the FGR fetus is based on a detailed biometric and anatomic assessment evaluating for growth, chromosomal and structural defects, and congenital infections. Compared to other fetal biometric parameters, the AC is regarded as the most accurate measurement with the highest sensitivity and negative predictive value for identifying FGR. However, assessment of the estimated fetal weight (EFW) requires additional measurement of the HC and femur length.

The assessment of fetal growth velocity by serial ultrasound evaluation of AC and EFW is superior to single estimates of AC and EFW in the prediction of FGR. Moreover, it is important to assess the amniotic fluid volume. Placental insufficiency and fetal hypoxemia cause fetal oliguria and consequently oligohydramnios. Decreased amniotic fluid volume is regarded as an early sign of IUGR and oligohydramnios is defined as the presence of a largest vertical pocket of amniotic fluid less than 2 cm or amniotic fluid index (AFI) less than 5 cm.

The next essential step in the diagnostic process of FGR is based on Doppler blood-flow studies. It is well established that Doppler ultrasound assessment of the uterine and umbilical arteries helps to distinguish growth restricted fetuses due to impaired placentation from constitutionally small fetuses. In FGR fetuses, abnormal blood flow in the umbilical artery usually precedes other cardiovascular adaptations. Abnormal Doppler findings indicative of uteroplacental insufficiency include increased impedance with absent or reversed end-diastolic flow in the umbilical artery.

The further evaluation of the fetal cardiovascular system involves the assessment of the middle cerebral artery and the ductus venosus. When redistribution occurs, ductus venosus blood flow is usually normal and biophysical abnormalities are generally not clinically apparent. Abnormal ductus venosus blood flow indicates a decompensation of the cardiovascular system, which is followed by abnormalities in biophysical parameters. The biophysical profile consists of fetal tone, breathing movements, gross body movements, amniotic fluid volume assessment, and CTG monitoring, and it reflects the fetal behavioral status. The deterioration of the fetal biophysical profile associated with Doppler evidence of right heart failure indicates intrauterine fetal jeopardy. Optimizing the time of delivery, in which iatrogenic intervention should be delayed to avoid the risks of premature birth without increasing the risks of exposure to an

adverse intrauterine environment, remains a challenge for perinatologists.

Perinatal mortality and long-term morbidity, including neurodevelopmental delay, is considerably increased in FGR fetuses with evidence of abnormal ductus venosus blood flow. The delivery decision should not be based merely on the umbilical artery waveform alone but mainly on the combination of abnormal venous Doppler indices and abnormal biophysical profile parameters. Furthermore, if early delivery is required, the gestation- and birth weight-specific charts produced by a study by Draper et al. should be used to determine the likelihood of survival.

Preterm Birth

Stress experienced during pregnancy increases the risk of preterm labor. Preterm birth, i.e. delivery before 37 weeks of gestation, occurs in approximately 10% of all pregnancies constituting the leading cause of neonatal morbidity and mortality. It is noteworthy that the incidence of premature labor remains unaffected by improvements in social health care and socioeconomic level observed in Western countries during the last 50 years. A substantial body of evidence has emphasized the role of stress as a major risk factor for preterm delivery. Furthermore, a correlation has been documented between maternal stress, either physical or emotional and premature delivery and it is proposed that the earlier in pregnancy the adversity is experienced, the earlier parturition occurs.

It has been suggested that premature activation of placental CRH gene expression in response to stressors induces early fetal neuroendocrine maturation and premature labor. Indeed, maternal and placental endocrine dysfunction triggered by a variety of stressors and the consequent occurrence of fetal stress may generate the process leading to preterm delivery. Although the early expulsion of the stressed FGR fetus from an adverse intrauterine environment carries the evolutionary advantage of genome maintenance it has the cost of increased risk of perinatal morbidity and mortality as well as the development of dysmetabolic syndrome in adulthood.

Restriction site polymorphisms

The differences in the DNA base sequence of a gene identified by fragmentation of the gene with a DNA-cutting enzyme.

Thrombus

A blood clot; formed by platelet aggregation and the conversion of soluble fibrinogen to an insoluble mesh of polymerized fibrin.

Molecular Biology
Physiology
Pathophysiology
Epidemiology

Glossary

<i>Acute-phase reactant</i>	A blood constituent (e.g., C-reactive protein, leukocytes, fibrinogen, or albumin) that shows a transient change in concentration in response to infection or inflammation.
<i>Endothelium</i>	The tissue lining the inside surface of blood vessels.
<i>Fibrinolytic activity</i>	A measure of the ability of blood to dissolve a thrombus.
<i>Mendelian randomization</i>	An approach to testing causal associations in epidemiology using the influence of a common genetic polymorphism on the risk factor being studied.
<i>Monocyte/macrophage</i>	A type of phagocytic leukocyte.

Fibrinogen is a large protein synthesized by the liver that makes up some 5% of total plasma protein. Various stimuli, including injury, activate a sequence of clotting factors that cause soluble fibrinogen to be converted enzymically to fibrin, an insoluble polymer matrix that is the structural component of blood clots. Raised fibrinogen levels indicate an increased risk of ischemic heart disease and stroke. It is uncertain whether fibrinogen is a risk factor that causes cardiovascular disease (CVD) or a marker of developing disease. Fibrinogen is an acute-phase reactant, and the circulating level increases in response to infection, chronic inflammation, smoking, and other environmental stressors.

Molecular Biology

Structure

Fibrinogen is a large soluble protein of approximately 340 kDa. It is made up of two tripeptide units, each

Figure 1 High-resolution electron micrograph of a fibrin polymer matrix. Red blood cells are trapped within the mesh. Courtesy of Dr. D. W. Gregory, University of Aberdeen/Wellcome Trust Medical Photographic Library.

consisting of $A\alpha$, $B\beta$, and γ peptides held together by covalent disulfide bonds. The three-dimensional structure has the form of a rod of dimensions 7×48 nm with a globular domain at each end and a third globular domain at the center of the rod, where the two units are joined together by further disulfide bonds. Free N-terminal residues project radially from the central domain. This negatively charged region prevents the aggregation of fibrinogen molecules by electrostatic repulsion. Fibrin is formed when the four N-terminal peptides are cleaved to release fibrinopeptides A and B. With the loss of the negatively charged peptides, staggered end-to-end polymerization takes place to produce fibrin fiber bundles (Figure 1). The clot is completed by the reinforcement of the fibers with covalent cross-links. More than 20 enzymes and protein cofactors are involved in clot formation and dissolution. Blood platelets interact with and possess receptors for fibrinogen. These nonnucleated bodies originate from bone marrow cells (megakaryocytes) and circulate at a concentration of some $150\text{--}500\,000\text{ mm}^{-3}$.

Biosynthesis and Genetics

Fibrinogen is synthesized primarily by hepatic parenchymal cells and to a lesser extent by megakaryocytes. The fibrinogen peptides are encoded on chromosome 4. A 50-kb span contains the genes for the $A\alpha$, $B\beta$, and γ chains separated by untranslated base sequences. These promoter sequences appear to coordinate the expression of the three genes. After translation and assembly, with the formation of the disulfide bonds, the molecule is glycosylated before release into the circulation from secretory vacuoles.

Serious congenital abnormalities of fibrinogen biosynthesis are uncommon. Absent or very low levels of fibrinogen have been identified, but congenital

hyperfibrinogenemia has not. Major abnormalities are probably due to translation, transcription, or secretion defects rather than gross fibrinogen gene defects. Less dramatic abnormalities are associated with bleeding or thrombosis, or may be asymptomatic. Several restriction site polymorphisms exist on the α and β genes. Common genetic variants have been shown to account for some 15% of within-population differences in plasma fibrinogen levels and may explain susceptibility to CVD in some families. Genetic epidemiology uses this variation in association studies of unrelated individuals to test the causal link with coronary heart disease (CHD), applying the method of Mendelian randomization.

Physiology

The Clotting System

The clotting, or coagulation, system functions to maintain the integrity of blood vessels and is essential to homeostasis. Two mechanisms initiate formation of a thrombus: (1) injury of the vascular lining (endothelium) to expose anionic surfaces causes binding and activation of factor XII, the first step in the intrinsic pathway, and (2) exposure of the transmembrane protein factor III or tissue factor (TF) at the site of injury leads to the initiation of the extrinsic pathway (so called because it relies on a substance not usually present in the circulation).

The main reaction of the extrinsic pathway involves the binding of factor VII and calcium ions (Ca^{2+}) to the exposed tissue factor receptor to form the catalyst TF-VIIa-Ca^{2+} , which converts inactive factor X to active Xa. The cascade of four reactions in the intrinsic pathway also generates an increase in the local concentration of factor Xa. If each step in this pathway activates 100 enzyme molecules, the initial event will produce a signal amplified by 10^6 . The two clotting pathways lead to the formation of the same prothrombinase complex (Va-Xa-Ca^{2+} -phospholipid), which catalyses the hydrolysis of prothrombin to thrombin. Thrombin has three major roles: it splits fibrinopeptides A and B from the $A\alpha$ and $B\beta$ chains of fibrinogen to form fibrin and promotes the aggregation of platelets at the site of injury. The clotting process is self-controlling by means of inhibitory mechanisms in which thrombin and protein C are central.

Blood Platelets

Low platelet counts are associated with capillary bleeding, and high counts are associated with intravascular thrombosis. Platelet aggregation is initiated in two ways. First, thrombin and receptors on damaged endothelial cells cause the exposure of a receptor

for fibrinogen (integrin α_{IIb}/β_3 or glycoprotein GPIIb/IIIa) on the platelet membrane. Fibrinogen binds the activated platelet to other platelets or to collagen. Second, high shear conditions, such as those occurring in narrowed atheromatous vessels, activate a second receptor that binds von Willebrand factor (vWF). This glycoprotein is released by activated platelets to form links between platelets and to anchor the growing thrombus to the vessel wall. Aspirin inhibits the aggregation mechanism involving fibrinogen but not shear-induced aggregation involving vWF.

The Fibrinolytic System

The thrombus is broken down to restore normal blood flow by the proteolytic action of plasmin on the fibrin matrix when, for example, the wound has healed. This enzyme is converted from the inactive form by tissue plasminogen activator (t-PA), which is secreted by endothelial cells of the vessel wall. Fibrin degradation products are detectable in the blood of healthy individuals, indicating that thrombus formation and fibrinolysis proceed continually. Inhibitors of fibrinolysis include lipoprotein (a) and plasminogen activator inhibitor.

Blood Viscosity

The plasma level of fibrinogen is an important influence on the flow properties of blood. Plasma viscosity increases exponentially with fibrinogen concentration. Because blood contains cells, among which the erythrocyte (red blood cell) predominates at some $5 \text{ million mm}^{-3}$, it is a non-Newtonian fluid exhibiting an apparent viscosity depending on local flow conditions. Viscosity is lower when blood flow is turbulent and under high shear conditions; it is higher under the opposite conditions. The blood flow rate is inversely related to viscosity and directly proportional to the fourth power of the vessel diameter. A small change in diameter thus produces a large change in tissue perfusion.

Pathophysiology

Thrombus Formation

Thrombus formation is involved in several important causes of death and disability. Coronary thrombosis may precipitate sudden coronary death or heart attack, whereas cerebrovascular thrombosis leads to stroke. A small proportion of women possess an abnormally sensitive clotting system and an increased tendency to form venous thrombi in response to raised circulating estrogen levels with oral contraceptive use or in pregnancy. Clot-busting or thrombolytic

drugs, such as recombinant t-PA, administered within hours of heart attack are effective in restoring blood supply to the damaged heart muscle and in reducing subsequent mortality.

Atheroma Formation

The clotting system is involved in the slow evolution of atheroma, the plaques that produce arterial narrowing. Fibrinogen and fibrin are found in atherosclerotic lesions. Histological studies show that small thrombi formed at the vessel wall can be incorporated into the evolving plaque. Platelets or platelet fragments are detectable in many plaques. Fibrinogen and its degradation products interact with platelets, endothelial and smooth muscle cells, and monocytes. These processes include the transfer of cholesterol from lipoproteins and platelets to monocytes to form giant foam cells and their incorporation into the growing plaque.

Acute-Phase Reaction

The acute response to infection or inflammation includes an increase in plasma fibrinogen concentration. This is, in part, stimulated by a rise in monocyte secretion of interleukin (IL)-6, one of a group of inflammatory mediators known as the cytokines. An IL-6-responsive element has been identified in the promoter region of the β -fibrinogen gene, and IL-6 thus appears to be a major regulator of fibrinogen synthesis. The size of the inflammatory response appears to be tuned by a vagally mediated anti-inflammatory pathway. Parasympathetic outflow via cholinergic neurons inhibits release of pro-inflammatory cytokines from liver, spleen, and other organs of the reticuloendothelial system. The connection between the nervous and immune systems has been demonstrated in animal models employing direct electrical stimulation of the efferent vagus nerve.

The higher fibrinogen levels seen in smokers may be due to chronic inflammation of the pulmonary epithelium and consequent raised IL-6 production. Long-term low-level inflammatory processes may also be involved in atheroma development as a result of chronic asymptomatic infections, such as gastric *Helicobacter pylori* infection.

Epidemiology

Cardiovascular Epidemiology

It is not clear whether hemostasis is causally involved in early development of coronary atherosclerosis, as opposed to the thrombotic processes that precede an acute CVD event. Internationally, levels of hemostatic

factors reflect underlying rates of CHD. Fibrinogen levels measured around 1980 were high in Czechoslovakia and Finland and low in urban Gambia. Mean fibrinolytic activity was highest in Gambia, intermediate in Scotland, and lowest in Finland. Plasma fibrinogen measured in the United States and Japan in 1987 showed substantially higher levels in White American men than in Japanese men. The difference was evident in nonsmokers; among Japanese nonsmokers mean fibrinogen was 2.2 g l^{-1} , whereas among American nonsmokers it was 2.8 g l^{-1} . These ecological associations, which parallel rates of disease, could be the product of cause or consequence.

At the individual level, a high plasma fibrinogen concentration in adulthood has been shown to predict CVD in a meta-analysis of 31 large cohort studies. Other hemostatic factors, including factor VII, white blood cell count, plasma viscosity, and fibrinolytic activity, predict CHD, although the evidence is less extensive. Fibrinogen level may be a mediator of the relationship between smoking and CVD. Likewise, the alcohol–fibrinogen relationship is consistent with the protective effect of moderate alcohol consumption on heart attack risk, and the fibrinogen level is lower in those taking regular leisure time physical activity. Fibrinogen remains predictive of CVD after taking into account smoking, blood pressure, body mass index, and serum cholesterol level. However, from prospective observational studies this evidence does not constitute proof of causation. The alternative interpretation, that fibrinogen is not a causal factor but a marker of the disease process, remains plausible. One deficiency in the evidence is the lack of fibrinogen-lowering trials that might demonstrate reduction of coronary risk.

Mendelian Randomization

Evidence that fibrinogen, and by implication hemostasis, is not causal for CVD comes from genetic epidemiology. Employing the method of Mendelian randomization, the lifelong influence of a common genetic variant in the promoter region of the β -fibrinogen gene that raises the plasma fibrinogen level was found to be without effect on CHD risk. In the same large case-control study, as in many other observational studies, plasma fibrinogen levels were substantially higher in coronary cases. The conflicting findings for phenotype and genotype suggest that plasma fibrinogen is raised as a result of the presence of developing atherosclerotic plaques. If replicated, the conclusion that raised fibrinogen is a consequence, rather than a cause of disease, becomes more likely.

Infancy and Childhood

Poor intra-uterine and early postnatal development are important elements in the genesis of adult disease. In this context, poor early growth and poor childhood socioeconomic conditions are related to elevated fibrinogen levels in adulthood. In addition, height in adulthood (reflecting early environment and genetic endowment) is inversely related to fibrinogen level and to cardiorespiratory mortality risk. These findings are consistent with the long-term *in utero* and childhood influences on CVD risk. It remains unclear whether the association with hemostatic factors is a direct result of early life conditions or the indirect consequence of accelerated disease processes that raise fibrinogen levels secondary to damage of the arterial wall. If the latter explanation emerges as the correct understanding, the measurement of hemostatic factors will remain important as a marker of subclinical disease in studies of the early origins of CVD.

Social Position and Psychosocial Factors

Plasma fibrinogen level is related to several social and psychosocial factors in adulthood. This is consistent with a contribution of hemostasis to the high rates of coronary disease experienced by people in unfavorable socioeconomic circumstances or, alternatively, with plasma fibrinogen being a marker of socially patterned disease processes. Mean fibrinogen levels are strongly and inversely related to grade of employment in the British civil service (Figure 2) and to social class based on occupation in a stratified sample of the population of England and Wales. Among civil servants, approximately one-half of the inverse association with social position was accounted for by health-related behaviors and degree of obesity.

Low job control, a measure of an adverse psychosocial work environment, has been linked to higher fibrinogen levels in both sexes in several studies. This association has been found when the work environment was assessed either subjectively, using standard self-completion questionnaires, or externally, by personnel managers. Complementing the link with adverse psychological conditions, positive affect is associated with a small plasma fibrinogen response to behavioral stress tasks (color-word and mirror tracing) in the laboratory.

It is plausible that psychosocial factors exert effects on the hemostatic system and thereby influence disease risk. Acute effects include increased platelet stickiness in the fight-or-flight response via increased circulating catecholamines. In a study of astronauts, spaceflight evoked raised urinary IL-6 on the first day

Figure 2 Plasma fibrinogen levels by employment grade (the Whitehall II study). but not on other days before or after launch, which is consistent with a psychological explanation because infection does not appear to be implicated. Cytokine release in response to psychosocial stimuli, and thereby increased fibrinogen synthesis, is feasible in view of the observation that mRNA for IL-6 is expressed within the brain. Over decades, such small effects may add to the formation of arterial plaques to increase risks of heart disease and stroke.

Glossary

<i>Allodynia</i>	Pain produced by normally nonpainful stimulation such as touch, gentle pressure, cold, or gentle joint movement.
<i>Central sensitization</i>	The development within the central nervous system of an exaggerated, pathological response to a stimulus that was originally innocuous, which depends on plasticity in function of <i>N</i> -methyl-D-aspartate (NMDA) glutamate receptors. Abnormally increased pain sensation.
<i>Hyperalgesia</i>	Class of glutamate receptors that act as ion channels characterized by their affinity for NMDA that are crucial for neural plasticity.
<i>N-methyl-D-aspartate (NMDA)-receptors</i>	The perception of pain.
<i>Nociception</i>	An unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage.
<i>Pain</i>	Discrete areas of hyperalgesia/allodynia where localized pressure will elicit pain.
<i>Tender points</i>	A frequency-dependent increase in the nervous system response to repeat stimulation thought to be dependent on glutamate and NMDA receptors in the dorsal horn of the spinal cord; temporal summation to pain produced by repeat stimulation.
<i>Wind-up</i>	

Introduction

Fibromyalgia is a disorder characterized by chronic widespread pain and tenderness to light palpation, sleep disturbance, and chronic fatigue. A diagnosis of fibromyalgia is made by the presence of diffuse

tenderness to light palpation in nonarticular soft tissues in a characteristic distribution in the absence of specific laboratory or radiological abnormalities, along with a history that typically includes exposure to significant stressors. Fibromyalgia can occur as an isolated condition, sometimes termed primary fibromyalgia, or it may occur in the presence of other painful conditions such as rheumatoid arthritis, a condition known as secondary fibromyalgia. In addition to the core features of chronic widespread pain and fatigue, patients are typically afflicted by a variety of other symptoms involving multiple organ systems, which has led in turn to the development of a more comprehensive construct: the fibromyalgia syndrome.

Background

The current concept of fibromyalgia is primarily derived from the work of Gowers and Stockman, who, in 1904, proposed that chronic widespread pain likely resulted from fibrositis, or diffuse inflammation of fibrous connective tissues. Subsequent analysis of said tissues has failed to demonstrate such changes, and, in fact, no peripheral pathology has been elucidated to date, despite extensive investigations. Given the lack of inflammation, the name was subsequently changed to fibromyalgia, which literally translated means simply pain in the muscles and fibrous tissues. The diagnostic criteria for classification and research purposes were formalized by the American College of Rheumatology, based on findings of the Multicenter Criteria Committee in 1990, which rely on the presence of discrete areas of tenderness to light palpation occurring diffusely in a primarily axial distribution that have been present for a minimum of 3 months (see [Figure 1](#)).

In the original documentation of the disorder, patients with fibromyalgia were noted to experience, in addition to chronic widespread pain, symptoms in multiple systems including disturbed bowel function, genitourinary problems, and allergic phenomena such as sinus drainage and congestion. An increased incidence of affective- and anxiety-related symptoms is also well known. More recently, the Canadian Case Definitions has been published, which places an increased emphasis on a variety of neurological phenomena associated with the disorder, including non-dermatomal paresthesias, headache, temporospatial dysmetria, and restless legs syndrome. In addition, patients frequently complain of cognitive dysfunction (commonly referred to as “fibro fog”) characterized

Figure 1 A diagnosis of fibromyalgia is based on (1) the presence of chronic widespread pain of at least 3 months duration in a distribution above and below the waistline, on the left and right sides of the body, and in a primarily axial distribution and (2) pain on palpation with a 4-kg force in 11 of 18 tenderpoints.

by impaired concentration and short-term memory consolidation, impaired speed of performance, inability to multitask, and frequent cognitive overload.

The combination of a lack of readily demonstrable pathology to which symptoms might be ascribed and the dependence on subjective patient report has fueled much of the controversy surrounding fibromyalgia and led to large segments of the medical community dismissing such patients as neurotic complainers aspiring to fashionable diagnoses. However, although the exact pathology underlying the disorder's cardinal feature, namely, chronic widespread pain, remains one of medicine's enduring mysteries, recent advances have shed increasing light on the nature of the disorder. As investigations into potential peripheral pathologies have remained largely fruitless, increasing attention has been focused on mechanisms within the central nervous system. Accordingly, fibromyalgia is increasingly conceptualized as an aberration of information processing in pain-related pathways and thus is considered a form of central sensitization.

Epidemiology

Fibromyalgia is a common condition with an estimated prevalence of 2% of the general population: 3.4% for women and 0.5% for men. Although all ages are affected, the prevalence increases with age, reaching greater than 7% in women aged 60 to 79 years. Fibromyalgia is the second most common diagnosis in rheumatology clinics. Given that the vast majority of fibromyalgia patients are female, many

researchers have suggested that gender-specific factors likely play a role in the development and/or maintenance of symptoms.

Etiology: The Role of Stress

Fibromyalgia has been characterized as a stress-related disorder due to the recognition of its frequent onset after acute or chronic stressors and apparent exacerbation of symptoms during periods of physical or emotional stress. Factors associated with the onset of fibromyalgia include severe infectious illness, physical trauma, and severe emotional distress. In addition, many of the comorbid conditions that affect fibromyalgia patients are likewise considered to be stress-related disorders, including irritable bowel syndrome, chronic fatigue syndrome, interstitial cystitis, and such neuropsychiatric disorders as depression and posttraumatic stress disorder. Patients with fibromyalgia also report a higher incidence of adverse early life events than unaffected individuals. While the experience of adverse early life events has been demonstrated to produce a variety of changes to the neuroendocrine function and to have an adverse impact on the brain limbic system in susceptible individuals, the specific contribution of these events to the etiology of the disorder is not clear, nor is there a strict correlation between the experience of adverse early life events and the development of chronic widespread pain.

While a number of phenomena associated with fibromyalgia have been attributed to the stress of chronic pain, basic science has demonstrated that the experience of chronic stress per se produces harmful sequelae such as disrupted immune and neuroendocrine function, alterations of neurotransmitter release, and damage to the very substance of the brain itself. These observations have in turn informed some of the more recent theoretical considerations concerning the etiopathogenesis of the disorder, which are explored later. In addition, a growing body of evidence supports a component of genetic heritability in the development of the disorder. Taking into account the contribution of both genetic as well as environmental factors, the development of fibromyalgia likely results from a combination of genetic predisposition and subsequent exposure to critical environmental conditions that must reach a critical load in order to initiate the changes that result in the development of chronic widespread pain and tenderness. (One might therefore suggest that what fibromyalgia represents is a rather bizarre form of allostasis.) As such, individuals with high susceptibility would require little or no stress in order for symptoms to develop, while others might endure years of duress prior to symptom onset.

This suggestion raises the possibility of a prodromal period during which subtle changes are occurring within the susceptible nervous system during periods of prolonged stress.

Experimental Findings

An unfortunately intransigent misconception among many clinicians is the notion that the patient with fibromyalgia essentially has nothing wrong with him or her, a position that stems in large part from a frustrating lack of readily demonstrable pathology in the soft tissues or blood. On the contrary, research has demonstrated a variety of abnormalities are in fact associated with the disorder, which are detailed below.

Polymodal Sensitivity

Results from studies examining responses to experimental stimulation have shown that fibromyalgia patients display sensitivity to pressure, heat, cold, and electrical and chemical stimulation. Experiments examining pain regulatory systems have shown that fibromyalgia patients also display a dysregulation of diffuse noxious inhibitory control, an exaggerated wind-up response, and an absence of exercise-induced analgesic response. Together, these results point to dysregulation of the nociceptive system at the central level.

Sleep Disturbances

The first objective findings associated with the disorder were reported in 1975 by Moldofsky and colleagues, who reported the presence of anomalous alpha wave activity (typically associated with arousal states) on sleep electroencephalogram (EEG) in fibromyalgia patients during non-rapid eye movement sleep. In fact, by consistently disrupting stage IV sleep in young, healthy subjects, Moldofsky was able to reproduce a significant increase in muscle tenderness similar to that experienced by fibromyalgia patients but that was resolved when the subjects were able to resume their normal sleep patterns. Since that time a variety of other EEG sleep abnormalities has also been reported in subgroups of fibromyalgia patients. While chronic sleep disruption has been documented to disrupt normal brain function and produce a variety of deleterious neuroendocrine and metabolic consequences, the specific mechanism whereby increased tenderness might result remains to be determined, as does the exact relationship of sleep disruption to the disorder, whether as a contributing factor or rather an additional manifestation of an underlying pathology.

Neuroendocrine Disruption

Patients with fibromyalgia have been demonstrated to have a disruption of normal neuroendocrine function, characterized by mild hypocortisolemia, hyperactivity of pituitary adrenocorticotropin hormone release in response to challenge, and glucocorticoid feedback resistance. A progressive reduction of serum growth hormone levels has also been documented – at baseline in a minority of patients, while most demonstrate reduced secretion in response to exercise or pharmacological challenge. Other abnormalities include reduced melatonin secretion, reduced responsiveness of thyrotropin and thyroid hormones to thyrotropin-releasing hormone, and a mild elevation of prolactin levels with disinhibition of prolactin release in response to challenge and hyposecretion of adrenal androgens. These changes might be attributed to the effects of chronic stress, which, after being perceived and processed by the central nervous system, activates hypothalamic corticotropin-releasing hormone neurons. Thus, the multiple neuroendocrine changes evident in fibromyalgia have been proposed to stem from chronic overactivity of corticotropin-releasing hormone releasing neurons, resulting in a disruption of normal function of the pituitary-adrenal axis and an increased stimulation of hypothalamic somatostatin secretion, which, in turn, inhibits the secretion of a multiplicity of other hormones.

Sympathetic Hyperactivity

Functional analysis of the autonomic system in patients with fibromyalgia has demonstrated disturbed activity characterized by hyperactivity of the sympathetic nervous system at baseline with reduced sympathoadrenal reactivity in response to a variety of stressors including orthostatic challenge and mental stress. Fibromyalgia patients demonstrate lower heart rate variability, an index of sympathetic/parasympathetic balance, indicating sustained sympathetic hyperactivity, especially at night. In addition, plasma levels of neuropeptide Y, which is colocalized with norepinephrine in the sympathetic nervous system, have been reported to be low in patients with fibromyalgia. Incongruent with this finding, there have been inconsistent reports of low, normal, and high circulating levels of epinephrine and norepinephrine. Administration of interleukin-6, a cytokine capable of stimulating the release of hypothalamic corticotropin-releasing hormone, which in turn stimulates the sympathetic nervous system, resulted in a dramatic increase in circulating norepinephrine levels and a significantly greater increase in heart rate over baseline in fibromyalgia patients as compared to healthy controls.

Cerebrospinal Fluid Abnormalities

Perhaps the most reproducible laboratory finding in patients with fibromyalgia is an elevation in cerebrospinal fluid levels of substance P, a putative nociceptive neurotransmitter. While this finding is intriguing, a review of the literature reveals that an elevation in substance P levels is not specific to this disorder, nor has any correlation between these levels and clinical pathology been determined. In addition, metabolites for the monoamine neurotransmitters serotonin, norepinephrine, and dopamine – all of which play a role in natural analgesia – have been shown to be lower, while reports of changes in cerebrospinal fluid concentrations of endogenous opioids (i.e., endorphins and enkephalins) have been contradictory. The mean concentration of nerve growth factor, a substance known to participate in structural and functional plasticity of nociceptive pathways within the dorsal root ganglia and spinal cord, has been reported to be elevated in fibromyalgia patients. In addition, evidence for increased excitatory amino acid release within cerebrospinal fluid has also been reported, with a correlation between levels for metabolites of glutamate and nitric oxide and clinical indices of pain.

Brain Imaging Studies

Evidence of abnormal brain involvement in fibromyalgia has been provided via functional neuroimaging. The first findings reported a decreased blood flow within the thalamus and elements of the basal ganglia and mid-brain (i.e., pontine nucleus) in patients with fibromyalgia. Differential activation in response to painful stimulation has also been demonstrated. Brain centers showing hyperactivation in response to noxious stimulation include such pain-related brain centers as the primary and secondary somatosensory cortex, anterior cingulate cortex, and insular cortex, while relative hypoactivation at subjectively equal pain levels appears to occur within the thalamus and basal ganglia. In addition, patients exhibit neural activation in brain regions associated with pain perception in response to nonpainful stimuli, in such areas as the prefrontal, supplemental motor, insular, and cingulate cortices. Some of the brain abnormalities seem to be amenable to pharmacological intervention, as a few studies have reported changes on neuroimaging in response to effective therapeutic intervention, although replication of such findings is needed. Patients with fibromyalgia also have evidence of hippocampal disruption indicated by reduced brain metabolite ratios and reduced gray matter concentration. Finally, positron emission tomography using radiolabeled DOPA, a precursor to dopamine synthesis,

has demonstrated a diffuse reduction in monoaminergic (i.e., dopamine, norepinephrine, and epinephrine) metabolism specifically in brain areas in which dopamine plays a critical role in natural analgesia, including the anterior cingulate cortex, insula, and thalamus.

In summary, the abnormalities associated with fibromyalgia show evidence of enhanced nociception associated with increased cortical excitability (as evidenced by abnormal arousal patterns on sleep EEG and increased activation in response to stimulation), subtle changes in brain chemistry, and a dysregulation of both arms of the stress response, i.e., the HPA axis and the sympathetic nervous system. As a review of these findings might suggest, one problem facing both patients and clinicians is that the type of abnormalities reviewed herein are generally detected by assays not typically available to primary care or even tertiary referral clinics. Given the lack of more readily demonstrable pathology, the difficulty that the medical culture has had coming to terms with fibromyalgia and related conditions seems to stem from the pervasive philosophical tradition of Cartesian dualism, in which human phenomena are categorized as belonging to one of two domains, i.e., psyche or soma – the mind or the body. Thus, if an individual presents to a clinician with somatic complaints for which no pathological change is evident in the organ from which the symptoms seem to originate, and if stress appears to play a contributory role, then the patient is liable to be dismissed as somatizing or expressing psychic distress by way of physical symptoms. This unfortunate attitude on the part of uninformed clinicians represents what essentially amounts to a medical form of being politically correct in suggesting that a patient's problems are all in his or her head – a phrase that tacitly avoids the pejorative and clinically irrelevant label “crazy”.

Hypothetical Mechanisms of Abnormal Pain Processing

While the preceding findings are intriguing, the fact is that the exact mechanism of enhanced nociception in fibromyalgia remains a matter of debate and continuing inquiry. Accordingly, the following represents a synopsis of some hypothetical considerations regarding the potential pathologies that might contribute to the phenomenon of enhanced nociception.

There exists a school of thought that considers the pain of fibromyalgia to represent a primarily psychic phenomenon. Accordingly, those who ascribe to this perspective consider the enhanced nociception displayed by fibromyalgia patients to represent a form of secondary hyperalgesia, attributed to such

processes as hypervigilance or increased attention to somatosensory stimulation suggesting a perceptual style of amplification. This conclusion is derived in part from the consistent observation of increased activation of the anterior cingulate cortex, which plays a role in both the attentional and affective, or emotional, dimensions of pain perception. Enhanced activation of the anterior cingulate cortex in response to stimulation has also been demonstrated in another stress-related disorder characterized by enhanced somatosensory perception: irritable bowel syndrome.

On the other hand, the hyperalgesia and other forms of polymodal sensitivity that characterize the disorder have been conceptualized as a form of central sensitization in which elements of the central nervous system have become pathologically sensitive to stimulation, thereby making stimuli that were previously innocuous (light touch, for example) excruciating. The phenomenon of central sensitization has been demonstrated to depend on the plasticity in function of *N*-methyl-D-aspartate (NMDA) subtype glutamate receptors, which play a fundamental role in the flow of information within the brain and spinal cord. In support of this notion, it has been demonstrated that a large subgroup of patients respond to very small doses of the anesthetic ketamine, which at sufficient doses antagonizes NMDA receptors, with dramatic reductions in the painful symptoms. It is then intriguing that NMDA receptors play a critical role in pain perception, specifically within the hippocampus and anterior cingulate cortex, wherein a variety of stress-related factors such as corticotropin-releasing hormone, cortisol, norepinephrine, substance P, and histamine contribute to neuronal excitability specifically by enhancing NMDA receptor activity. Thus, the pain of fibromyalgia (and perhaps other related disorders) might stem from stress-related changes within brain centers involved in overlapping mechanisms of nociception (i.e., attentional and affective dimensions), in which stress-related factors reduce the threshold for excitation. As such, these changes provide a credible organic basis for what might otherwise be appreciated as psychic phenomena.

A relative increase in the amount of information flowing out of the body and toward the brain might also result in enhanced pain perception. One naturally expects this in scenarios involving tissue damage, whether related to mechanical causes (as in an injury or a degenerative condition such as arthritis) or a chemical or thermal exposure. Likewise, inflammatory processes result in the release of various chemicals within affected tissues that sensitize peripheral pain receptors (nociceptors), thereby amplifying the flow of information from the area of inflammation.

The adaptive value of such an increased amount of painful information originating from injured tissue is clear: the organism protects the area and allows it to heal. On the other hand, no such peripheral pathology has been described in fibromyalgia; therefore, an area of intense focus regarding the potential source of increased information flowing toward the brain has been potential pathological changes within the dorsal root ganglion and dorsal horn of the spinal column, which collectively represent the interface between the peripheral and central nervous systems. Both of these regions contain high densities of NMDA receptors, which are thought to contribute substantially the phenomenon of wind-up, and both have been demonstrated to undergo pathological transformation under certain conditions, thereby resulting in hyperalgesia and allodynia in the affected area. Intriguingly, recent investigations using rat models have demonstrated that stress exposure results in increased metabolic activity within the dorsal horn. However, the relevance of these findings to fibromyalgia remains unknown.

Somatosensory information processing represents a two-way flow of information within the spinal cord: information concerning the status of the body is transferred from the peripheral nervous system to the central nervous system and ascends the spinal cord toward the brain, while a variety of filtering mechanisms descend from the brain to modulate the amount of information transferred specifically within the dorsal horn. The vast majority of neurons that carry descending inhibition run along tracks within the dorsal spinal column (i.e., the part furthest toward the back). Research has demonstrated that interruption of the dorsal descending systems leads to hyperactivity of pain-related neurons within the spinal cord characterized by an increase in background activity, lowering in stimulation threshold, and increase in response magnitude to noxious stimuli. Collectively, the findings suggest that if such an interruption were to occur in humans, such impairment would likely result in spontaneous deep pain, tenderness to palpation, and hyperalgesia of deep tissues – all of which characterize patients with fibromyalgia. Accordingly, some researchers are focused on determining the potential contribution of restrictive lesions, specifically within the cervical spinal cord, to the experience of chronic widespread pain. Likewise, an increase in descending facilitation involving medullary brain centers might also contribute to the amplification of sensory information.

The apparent dysregulation of the sympathetic nervous system detailed previously has led to the hypothesis that fibromyalgia might represent a sympathetically maintained pain syndrome. In support of this notion,

proponents of the hypothesis observe that, like other so-called sympathetically maintained pain conditions (e.g., complex regional pain syndrome, or reflex sympathetic dystrophy), the pain associated with fibromyalgia may be characterized by its frequent posttraumatic onset and by the presence of chronic stimuli-independent pain accompanied by allodynia, paresthesias, and distal vasomotor changes. Limited reports suggest that fibromyalgia pain may be aggravated by peripheral administration of epinephrine. Historically speaking, it has been generally considered that sympathetically maintained pain is alleviated by maneuvers intended to block sympathetic activity, and there are (again, limited) reports reflecting that fibromyalgia patients respond to these as well. More recently, however, the contribution of sympathetic activity to those conditions traditionally considered to represent sympathetically maintained pain conditions has become a matter of some contention, while the specific mechanism whereby sympathetic activation might contribute to the development of chronic widespread pain remains to be elucidated.

The most recent hypotheses concerning the nature of pain in fibromyalgia have to do with a disruption of natural analgesia within the limbic system involving the neurotransmitter dopamine. Stressful experience has been robustly demonstrated to disrupt the normal function of dopamine neurons, which in turn plays an important role in natural analgesia in such brain centers as the thalamus, basal ganglia, nucleus accumbens, insular cortex, and anterior cingulate cortex. Recent insights regarding the pharmacology of ketamine have demonstrated that the drug activates dopamine D2 receptors, which may then explain its efficacy in relieving symptoms of fibromyalgia when given at very low doses. Intriguingly, many of the brain centers that have been shown to be involved in fibromyalgia using functional neuroimaging are among the same brain centers in which dopamine plays a role in analgesia. Dopamine acts within the thalamus and insular cortex to recruit mechanisms of descending inhibition, while in the anterior cingulate cortex dopamine opposes the activity of NMDA receptors specifically involved in nociception. In addition, the reactivity of dopamine neurons is controlled by excitatory output from the hippocampus, which in turn is exquisitely sensitive to the effects of stress-related factors. A stress-related increase in neuronal excitability within the hippocampus would be predicted to suppress the reactivity of dopamine neurons, thereby producing a relative increase in painful sensations. Other neurotransmitters whose dysfunction has been proposed to contribute to the development of chronic widespread pain include serotonin and norepinephrine. In general,

medications that act chiefly to boost serotonergic activity have met with disappointing results, while those with mixed activity for serotonin and norepinephrine are somewhat more promising.

Future Directions

Among the current concepts driving investigations into the nature of fibromyalgia is the growing awareness that patients with fibromyalgia likely represent a homogenous population in which chronic widespread pain is the common denominator. This idea resonates with the conceptualization of two other categories of central nervous system disorders: epilepsy, which has as its common denominator stereotyped and uncontrollable movement stemming from pathology within a variety of brain centers, and depression, in which patients experience dysphoria stemming from the disturbance of a variety of neurohormonal factors. Thus, efforts to subclassify fibromyalgia patients along both organic and psychological lines are currently under way.

In order to effectively target the symptoms of a disorder for therapy, there must first be an understanding of the underlying pathology. In light of recent advances in our insights into the disorder, we indeed seem to be standing at the threshold of understanding. While the status of fibromyalgia as a bona fide disorder is a matter of continuing debate among the uninformed, the fact that major pharmaceutical companies have begun to develop large-scale trials to investigate the potential efficacy of existing drugs at relieving the various symptoms associated with the disorder is evidence of its increasing acceptance within the medical community as a whole. In general, there seems to be grounds for an increased sense of optimism regarding relief for patients, both from their symptoms and from the stigma previously associated with the diagnosis.

Emotional Stimulation and Epinephrine Secretion
The James–Lange Theory of Emotions
The Cannon–Bard Theory of Emotions
Contemporary Research on the Fight-or-Flight Response

Glossary

Cannon–Bard theory

A theory based on the work of the American physiologist W. B. Cannon and his student P. Bard. Their work indicated that portions of the brain stem and hypothalamus were essential for the expression of emotions and the peripheral physiological manifestations of the emotions.

Fight-or-flight response

A concept developed by W. B. Cannon that linked emotional expression to physiological changes in the periphery. Cannon emphasized the emergency function of the adrenal medulla in such situations. He reasoned that the increased discharge of epinephrine from the adrenal medulla stimulated increases in blood glucose and blood flow to skeletal muscles and a corresponding decrease in blood flow to the viscera.

James–Lange theory

A theory based on the independent work of the American psychologist W. James and the Danish physiologist K. Lange. The theory proposed that emotions resulted from afferent feedback from the periphery to the brain.

Emotional Stimulation and Epinephrine Secretion

Walter Cannon and his students and coworkers conducted an initial series of experiments from 1910 to 1911 that examined the link between emotional experiences and the secretion of epinephrine from the adrenal medulla. Employing an intestinal strip bioassay for the semiquantitative study of epinephrine secretion, he and his students determined that epinephrine secretion increased dramatically when a quiescent animal was exposed to a stressful or threatening stimulus. In addition, Cannon's laboratory used increases in glucose in the urine (glycosuria) as an indirect measure of epinephrine secretion with similar results. The connection between epinephrine secretion and increases in blood glucose led Cannon to write the following entry in his journal on January 20, 1911: "Got idea that adrenals in excitement serve to affect muscular power and mobilize sugar for muscular use – thus in wild state readiness for fight or run!" In time, "fight or run" was transformed into the more familiar fight or flight.

The initial description of the fight-or-flight response encompassed only the peripheral manifestations of the response, including a redirection of blood flow and

Table 1 Sympathetic-Adrenal Medullary Components of Fight-or-Flight Response

	<i>Physiological effects</i>	<i>Physiological consequences</i>
Heart	Increased rate	Increased rate of blood flow
	Dilation of coronary vessels	Increased availability of O ₂ and energy to cardiac muscle cells
Circulation	Dilation of vessels serving skeletal muscle	Increased availability of O ₂ and energy to skeletal muscle cells
	Vasconstriction of vessels serving digestive and related organs	Allows for shunting of blood to skeletal muscle cells
	Contraction of spleen	Increase in delivery of O ₂ to metabolically active tissues
Respiration	Dilation of bronchi	Increased availability of O ₂ in blood
	Increased respiratory rate	Increased availability of O ₂ in blood
Liver	Increased conversion of glycogen to glucose	Increased availability of glucose for skeletal muscle cells and brain tissue

increased delivery of O₂ and glucose to the skeletal muscles as an organism prepared to confront a threatening or stressful situation (Table 1).

It was not until the 1920s that Cannon began a series of studies on the central control of sympathetic-adrenal medullary activity. This work focused initially on studies of sham rage in decorticate cats. The findings pointed clearly to the posterior hypothalamus and basocaudal subthalamus as brain structures important for the elevated adrenal medullary discharge of epinephrine during sham rage. This line of research has continued to the present as investigators have used ever more refined anatomical techniques to define the central neural circuitry underlying emotional expression.

The James–Lange Theory of Emotions

At the turn of the twentieth century, the prevailing physiological theory of emotions was based on the independent efforts of the American psychologist William James and the Danish physiologist K. Lange. The James–Lange formulation was as follows:

1. An emotionally charged event occurs and stimulates sensory receptors.
2. Afferent nerve impulses reach the cerebral cortex and the event is perceived.
3. Efferent nerve impulses are directed to the skeletal muscles and the viscera and alter their levels of activity in preparation for the event.

4. Afferent nerve impulses from the periphery go once again to the cerebral cortex and the emotionally charged aspect of the event is perceived.

James emphasized the importance of visceral afferent signals and emotion, whereas Lange drew attention to the relationship between vascular afferent signals and emotion. This was the prevailing theory when Cannon and coworkers began to examine the neural basis for visceral and behavioral control during stressful experiences.

The Cannon–Bard Theory of Emotions

Cannon recognized that a critical test of the James–Lange theory would involve an examination of emotional expression in a subject with no visceral afferent feedback. In such an experiment, the critical link between visceral changes and the feedback required to stimulate the cerebral manifestations of the emotion would be broken. At least three prevailing lines of evidence pointed to the inaccuracy of the James–Lange theory: Sherrington had reported in 1900 that dogs exhibited intense emotions following complete destruction of the sympathetic and spinal sensory roots; later, Cannon and colleagues noted that cats remained emotionally responsive following surgical destruction of the sympathetic nervous system; and, finally, clinical case studies demonstrated that spinally transected patients retained their emotional responses despite being completely paralyzed below the neck.

Cannon was joined in this research effort by several of his students, most notably Philip Bard. Their efforts, beginning in the 1920s, changed the focus of research on emotions to include the central nervous system as the primary site for receiving sensory information, directing peripheral visceral and vascular changes, and generating the psychological manifestations of the experience.

Contemporary Research on the Fight-or-Flight Response

The study of the neural bases of emotions remains an active and exciting area of research to the present. Researchers continue to examine the neural circuits involved in the classic fight-or-flight responses of laboratory animals. Studies suggest that central command neurons within hypothalamic and brain stem nuclei project via sympathetic outflow systems to both the heart and the adrenal medulla. These collections of central command neurons may direct multiple sympathetically controlled neural and endocrine responses that subserve the fight-or-flight response. The midbrain periaqueductal gray region

has also been implicated in the physiological and behavioral changes attending the fight-or-flight response. In addition, research on the amygdala has revealed the importance of this brain region for memories of emotionally charged events. Finally, with the advent of imaging techniques (e.g., functional magnetic resonance imaging, fMRI) for studying regional brain activation in human subjects, it is now possible to determine which brain areas are activated during emotionally stimulating events in humans.

Cannon introduced the fight-or-flight concept to physiology and conducted some of the seminal studies in this area. It is impressive to note that his original research linking physiology with emotions is still frequently referenced more than 80 years later and that the fight-or-flight response continues to serve as a stimulating topic of inquiry for researchers in a variety of fields, including physiology, neuroanatomy, and psychology.

Firefighting as an Occupation

Physical Stress

Psychological Stress

Glossary

- 17-Ketosteroids** The metabolites of endogenous steroid hormones produced under sustained stress.
- Aerial ladder** A very high extension ladder on a hook and ladder truck, used for rescue and to reach the fire with water from above.
- Catecholamines** Endogenous hormones produced acutely under stress.

Ischemia

A condition of insufficient blood supply; in the heart, coronary artery ischemia may lead to angina (chest pain), arrhythmia (irregular heartbeat), or a heart attack.

Knockdown measures

Measures to suppress a fire, such as laying on water from a hose carried up a ladder.

Moonlighting

Holding a job or doing work in addition to one's regular employment, usually without the knowledge or approval of the principal employer; firefighters may have several days off between long shifts and often work other jobs to earn extra money.

Myocardial infarction

A heart attack, in which some of the heart muscle dies from lack of oxygen due to ischemia.

Personal protective equipment

The equipment used by firefighters during work to protect the individual workers from a hazard, as distinct from measures used to control the hazard itself; examples include self-contained breathing apparatus, gloves, helmet, and turnout gear (heavy coat and boots).

Firefighting as an Occupation

Firefighting is an intrinsically stressful occupation that attracts an unusual type of person. It is a commonplace saying that firefighters are unique people because they run into burning buildings when other people are fleeing them. The sad human toll of the World Trade Center attack, in which 121 firefighters died, trapped in the North Tower because their radios did not deliver warning messages due to lack of interoperability, demonstrates the risk that firefighters face in their work and their dependence on equipment and organization.

Firefighting, like most occupations involving emergency response, is characterized by prolonged periods of preparation for episodes of intensely stressful activity. Episodically, performance demands require exertion near the limits of human factors and cardiopulmonary conditioning. The risk of injuries is high in firefighting, as indicated by an increased hospitalization rate compared to other occupations for soft tissue injuries, burns, and overexertion. However, much of a firefighter's time is routine, spent in training and maintenance. The psychological stresses of firefighting include long periods of relative inactivity punctuated by highly stressful alarms and extremely stressful situations, such as rescues, as reflected in physiological and biochemical indicators. The literature on the health risks associated with firefighting is large and has been extensively reviewed with particular reference to human factors and ergonomics, chemical hazards, and work-related health outcomes.

The hazards associated with firefighting are changing in nature and magnitude. In the mid-twentieth century, the new composition of interior furnishings introduced new chemical hazards for firefighting, including combustion products from polyvinyl chloride (including phosgene, vinyl chloride) and acrylonitrile (including cyanide). In modern times, commercial and manufacturing facility fires may produce combustion products that are not well characterized and may not even be known. Although firefighting is generally becoming safer due to better and more available equipment and improved procedures, the terrible toll at the World Trade Center illustrates the growing potential for multiple fatalities and serious injuries when things go seriously wrong in ever-larger modern skyscrapers and large facilities.

Firefighters tend to take care of their own but on an informal basis. Firefighting is a close-in activity requiring teamwork under very threatening conditions, and firefighters tend to be very aware of the problems that their fellow firefighters might have in handling difficult situations. Individual firefighters who show early signs of illness are often selectively transferred out of active firefighting positions.

Physical Stress

Energy Requirements

Firefighting is a physically strenuous occupation that is sometimes performed under extreme environmental conditions. There are several components to the physiological demands of firefighting; these include the energy cost of performing firefighting activities, heat stress associated with heat from the fire, encumbrance by personal protection equipment, and psychological stress related to personal safety, protection of property, and protection of lives. The ergonomic demands of firefighting are extreme at peak activity because of high energy costs of activities such as climbing aerial ladders, the positive heat balance from endogenous and absorbed environmental heat, and encumbrance by bulky but necessary protective equipment. The use of personal protection equipment has imposed new physiological demands on firefighters despite the increased level of personal protection.

Physiological Stress

Firefighting is intrinsically stressful. Firefighters increase their urinary excretion of catecholamines (endogenous hormones produced acutely under stress) following workdays compared to days off. Paramedics, for whom job satisfaction was much less, had even higher levels of stress than firefighters. The urinary excretion of 17-ketosteroids (metabolites of endogenous steroid hormones produced under sustained stress) and catecholamines reflects perceived patterns of psychological stress and activity levels at the station.

Cardiovascular Stress

At the sound of an alarm, firefighters experience a degree of immediate anxiety because of the inherent unpredictability of the situation that they are about to encounter. Some investigators believe that the psychological stress experienced at this moment is as great and perhaps greater than any of the stresses that follow during the course of responding to an alarm. Studies of the cardiovascular response to the alarm itself show a marked and highly variable increase in heart rate during the response to a fire alarm, well before physical exertion begins at levels associated with maximal exertion or anxiety. Urinary catecholamine levels are particularly elevated among male firefighters during and after work in the alarm center, an assignment that is highly unpopular. There is also a gender-associated difference in the response, which is less pronounced in women. En route, hazardous traffic maneuvers and high noise levels from the sirens contribute to stress.

Fitness

Numerous studies have evaluated the fitness of firefighters and have shown fairly consistently that most firefighters are as fit or somewhat more fit than the general adult male population. They are not, however, fit to an athletically trained level. Recent studies of job performance requirements suggest that exercise programs for firefighters should be more comprehensive rather than emphasizing cardiovascular fitness and muscle strength, as is now the case.

An increasing number of female applicants are now competing for firefighting jobs. This has forced a re-evaluation of performance tests. As a group, women appeared to demonstrate lower scores on average than men in all performance items, but a subgroup of women performed nearly as well in some tasks. The overall difference in performance was attributed primarily to lower absolute lean body weight, which correlated most strongly and consistently with performance difference.

There is evidence that some firefighters may be stressed to the limit during the exertions of their work. Barnard et al. described an ischemic response in healthy young men, including firefighters, who engaged in sudden vigorous exercise without warm-up. They suggested a transient mismatch in oxygen supply and demand. Although this mechanism is probably not a cause of persistent or cumulative myocardial injury, it may play a role in unusual and emergent situations requiring sudden maximal exertion.

On this basis, it may be concluded that acute myocardial infarction occurring under these circumstances or shortly after maximal exertion in an emergency response may be directly associated with working as a firefighter. It could also be that such an event may happen at work to a firefighter with existing coronary artery disease, in which case it is reasonable to assume an association with firefighting activity. However, it is difficult to attribute myocardial infarction when off-service, hypertension, or chronic manifestations of coronary artery disease to firefighting at this time, given the available evidence.

Because of the high level of physical and psychological stress and the presence of chemical hazards known to injure the cardiovascular system, heart disease is a major occupational health concern in firefighting. Most studies of firefighters show no elevation in mortality from cardiovascular causes or, at most, a small excess risk. The healthy worker effect expected in such a highly selected group may be offset by greater than expected mortality. A healthy worker effect is more readily visible when comparisons are made to similarly selected occupational groups such as police. Although the findings of individual studies may differ, the pattern that emerges

after careful examination is that mortality from cardiovascular causes is not obviously increased in association with firefighting activity (either in terms of years of service or exposure opportunity).

Psychological Stress

There are many extraordinary sources of psychological stress in the life of a firefighter. The expectations for performance placed on firefighters are well beyond that of other civilian occupations, with the possible exception of police. Firefighters accept a level of personal risk beyond the range of normal human experience. Although this risk is controlled to the extent possible with fire equipment and personal protection, the reality of firefighting is that there is much that can go wrong at any fire and the course of a serious fire is often unpredictable. In addition to personal security, the firefighter must be concerned with the safety of others. A failed rescue or the death of a victim is so stressful that some firefighters who have experienced this cannot cope.

Studies of firefighters have shown high levels of job satisfaction and motivation compared to the general population, despite job-related anxiety and adjustment issues related to sleep deprivation, heavy workload or pace of work, constantly being on guard, unsatisfactory public interactions, rigid working conditions, personal risk, inconsistent instructions, and unforeseen situations. On the other hand, firefighters exert a great deal of control over their work in the selection of approaches to knocking down the fire and the use of protective equipment. They are continually faced with new challenges because every alarm presents a different story or situation.

However, firefighters who have experienced particularly threatening situations have demonstrated adverse emotional effects. Chief among these is loss of a life during a rescue attempt or the death or serious injury on the job of a fellow firefighter.

Firefighters have been intensively studied as a model population at risk for posttraumatic stress disorder. Posttraumatic stress disorder can significantly impair in their ability to maintain social and family relationships. Firefighters who do not show the full-blown posttraumatic stress disorder may still be affected by intrusive memories and anxiety. Incident debriefing sessions have been shown to be valuable and effective in assisting firefighters who would otherwise have difficulty coping and in reducing the short-term anxiety of those who would have been able to cope without assistance.

Firefighters are enmeshed in conflicting expectations and numerous technicalities related to the insurance industry, the legal profession, the fire service

administration and politics, labor-management relations, and building codes and inspection. Firefighters may be highly trained in the technicalities of fire suppression, but may become so enmeshed unwillingly in the nontechnical aspects of the occupation that they may experience great frustration. When inevitable mistakes happen or their judgment is questioned, firefighters may feel psychologically threatened because of the pressure to accommodate all these expectations and still manage during an evolving emergency.

On the other hand, firefighters enjoy many positive aspects of their work and social status. Firefighters have a high social standing and are considered to belong to the most highly skilled blue-collar occupation. The work itself is interesting, although highly routine between alarms. There is a high degree of autonomy and a heavy emphasis on teamwork and mutual support. Between shifts many firefighters moonlight (have second jobs). Firefighters enjoy the high esteem of the community, the admiration of other citizens, the aspirations of children as role models, and widespread support as unequivocally positive defenders of the public good.

Elements of the Stress Response

Factors Affecting the Stress Response

Glossary

<i>Clearance dynamics</i>	The temporal pattern of disappearance of a substance from the circulation, a body part, or the body.
<i>Interrenal</i>	The cells (tissue) located in the fish's head kidney responsible for secretion of corticosteroids; analogous to the adrenal gland of mammals.
<i>Ontogenetic stage</i>	Life history or life cycle stage.
<i>Osmo-regulatory</i>	Pertaining to water balance and related to hydromineral balance, which also includes electrolytes.
<i>Stressor</i>	The factor extrinsic to the fish that causes a stress response.

The physiological responses of fish to stressful situations are very similar to those of the other vertebrates, including humans. Perception of a threat is followed by a neuroendocrine cascade involving catecholamines and the corticosteroid cortisol. Together, these result in secondary stress responses that can be categorized as those concerned with provision of energy, hydromineral balance, the immune system, and pathways that affect behaviors. The psychogenically induced responses tend to be similar, irrespective of the stressful agent; specific stressors can also induce specific responses. While the inter- and intraspecific differences in characteristics of the stress response are ultimately determined by genetics, the animal's history and its extant environment determine the exact nature of the magnitude, duration, and consequences of the response to a particular stressor. Acutely stressful situations result in temporary impairment of necessary functions such as disease resistance, predator avoidance, and learning ability. In addition, prolonged or repeated exposure to stress can have negative effects on development, growth, and reproduction.

Elements of the Stress Response

The general physiological response of a fish to a stressful situation (stressor) is similar to that of the warm-blooded vertebrates. Upon perception of a stressor, the fish's central nervous system initiates a neuroendocrine cascade, resulting in release of catecholamines from chromaffin tissue and secretion of glucocorticosteroids from interrenal tissue (Figure 1). These affect other physiological systems (Figure 2). Of course, the nature of the stress response is quite polymorphic, and specific stressors also have specific consequences.

Stress Response Factors

Fish, including lamprey, produce catecholamines such as adrenaline. These hormones are important for the initial response to the stressor, assisting the fish in terms of energy and stamina. Compared to the steroid hormones, there is relatively little known about the function and dynamics of these peptides. They are secreted almost immediately following the onset of stress and have cardiovascular actions, increasing cardiac output and gill blood flow. Catecholamines have other metabolic actions such as elevating circulating levels of glucose and depleting liver glycogen; their effects can ultimately lead to elevated plasma lactate and altered free fatty acid concentrations. They also affect hydromineral balance, perhaps making the fish more leaky to water because of hypertensive actions, are diuretic, and influence drinking rate.

The jawed fish activate a hypothalamic-pituitary-interrenal axis (HPI) to secrete glucocorticosteroids when stressed. Some literature suggests that these hormones are important in agnathans, but the question is still open. Elasmobranchs produce 1 α -hydroxycorticosterone while the other groups of fish produce cortisol. Cortisol is secreted from interrenal tissue located in the head kidney within minutes after the onset of a stressor upon stimulation by adrenocorticotropin. Upon perception of a stressor, a neural response triggers the synthesis of corticotropin-releasing hormone (CRH) in the hypothalamus of the brain. This peptide is transported neuronally to the pituitary gland to stimulate production and release into the circulation of corticotropin (CTH; ACTH in mammals). There appear to be other brain peptides that may also have a similar action. CTH stimulates the release of cortisol into the blood from the interrenal cells located in the head (anterior) kidney. There is only a small reservoir of stored cortisol, so

new synthesis is also initiated. The rate of elevation of circulating cortisol varies greatly amongst the species of fish; increase can be seen in less than a minute in some species, while it appears to take hours in others. Cortisol also has a metabolic role during the stress response that serves to provide energy for fight-or-flight functions as well as for osmoregulation. It is essential for the active pumping of electrolytes such as sodium; it could thus help restore the water-ion imbalance consequent to stress by functioning as a mineralocorticoid (fish do not have a mineralocorticoid hormone like mammals). The glucocorticosteroids

might be beneficial to both resistance and recovery from stress. Cortisol is also immunosuppressive. The secondary stress responses are thus regulated via catecholamines and cortisol, acting via specific receptors for these hormones on tissues with target cells. The other elements of the HPI axis mentioned previously can also have direct effects independent of cortisol.

Responding to a stressor is an energetically costly process. That means that there is less energy available for other necessary life functions. The ability of fish to resist pathogens can be affected by stress. It appears that there can be enhancement of certain aspects of

the immune response at some times after exposure to a stressor, but depression of immune system capability tends to be a more general and prolonged response. Cells of the fish's immune system also likely manufacture the stress-related hormones CRH and CTH. Behaviors such as general activity, swimming performance, schooling, thermoregulation, orientation taxis, avoidance, chemoreception, feeding, predation evasion, aggression territoriality, negative conditioning, and learning are all affected by stress, primarily negatively. CRH and several other brain neurotransmitters (e.g., serotonin and dopamine) affect stress-related behavioral responses.

Adult Pacific salmon, *Oncorhynchus* spp., die shortly after spawning. Mature fish of these species have activated HPI axes as encountered during stress and hence elevated circulating levels of cortisol; their ability to clear cortisol from the circulation also appears to be impaired. These fish die from something akin to Cushing's syndrome as described for mammals – i.e., depletion of energy reserves, deterioration of structural tissues, and infection with pathogens resulting from hypercortisolemia.

Nature of the Stress Response

The severity and duration of a stressful encounter influences the magnitude and duration of the physiological stress response. Fish are able to recover from acute, nonlethal stressors. The physiological stress response is initiated within fractions of seconds of when a stressor is first perceived. The physiological events happening soon thereafter (within an hour or so), representing the activation or getting started aspects (alarm phase of stress), are stereotypical (i.e., more predictable) than those of the later stages (resistance and compensation/recovery). Depending on species and environmental conditions, some physiological and behavioral components of the stress response recover quite rapidly following cessation of the stressor, perhaps in minutes to hours. Energy-regarding factors tend to require several hours to return to prestress levels, while those concerned with the immune system, disease resistance, and learning may take days to weeks to recover completely. Magnitudes and durations of response are extremely varied among species as stressor types and durations.

Sequential exposure to acutely stressful events can lead to cumulative physiological responses; it depends on the frequency and severity of the stressor. If the number of repeated exposure to stressors is substantial and frequent enough, fish can compensate and adapt to the experiences. Exposure to less-frequent repeated stressors may not lead to cumulative effects for physiological stress response factors but can have long-term negative effects on a fish's ability to grow,

develop, or reproduce, presumably because there is less energy available for these functions.

Chronic exposure to a stressor can lead to exhaustion (death) or compensation if the stressor is not too severe. Severe but not acutely lethal stressors can result in eventual death via indirect mechanisms such as lowering resistance to pathogens. If fish have adapted to a chronically stressful situation, elements of the physiological stress response will likely not have the identical characteristics (e.g., circulating concentration, clearance dynamics, or rate of response) that they did in a resting state prior to the stressor. Also, the long-term fitness of a fish would be reduced under such circumstances.

When fish are exposed to more than one type of stressor simultaneously (e.g., crowding and temperature elevation), the closer a fish is to its tolerance limits to one stressor, the more severe will be the negative consequences of another concurrent stressor.

In general, the onset of stress in a fish can be determined, but science has not yet been able to establish how to determine when a fish has recovered from exposure to a stressor. In addition, we are not yet very capable of measuring the severity of a stressor. Higher order responses, such as resumption of feeding, appear to be better predictors of the absence of stress than clinical measurements regarding physiology.

Factors Affecting the Stress Response

The response to stressors is ultimately determined by the fish's genetic heritage. However, the stress response phenotype evident during any particular situation is strongly influenced by the fish's prior history, its extant environment, and its developmental stage.

Genetic Effects

There can be major interspecific differences in the nature of the stress response. While the basic elements are generally similar across groups, the magnitude and dynamics of the physiological responses to stressors can be quite different. Some species appear to respond quite slowly, at least in terms of the HPI axis, compared to others; there is a large variation in tolerance of stressors among different groups of fish. There are also genetic differences with reasonably high heritability between individuals within a species in the magnitude of the physiological response to stress. Similarly, there are genetically determined between-individual differences in tolerance of stressors, but it is unknown if these are related to the nature of the fish's physiological stress response.

The physiological stress response factors operate by activating and deactivating specific genes. The

genes affected differ between organs. Functional genomics (which genes respond and what they do) of the fish stress response is a relatively new field of study. The liver, immune system, and brain have received the most attention to date, and are all very strongly affected by the stress response.

Environmental Effects

A fish's prior history and its present environment can affect how it responds to stressors. While the initial stages of the hormonal responses to stress are reasonably invariant in different environments, the persistence of the response and its secondary and tertiary (i.e., whole animal) consequences are very dependent on the nature of the extant environment. Temperature is important in affecting the rates of reactions. Other water quality variables can also be important as controlling or directing factors. Prior experiences with stressors can also harden the fish and hence lessen the apparent severity of subsequent, similar stressors. Nutritional history of the fish can also modify the magnitude and/or dynamics of certain physiological factors of the stress response, particularly with reference to factors concerned with energy.

Importantly, some environmental challenges, albeit lethal, might not necessarily invoke a general HPI stress response. It appears that stressors that are perceived by the central nervous system are those that elicit such a response.

Developmental Effects

Fish at different ontogenetic stages of their life cycle may respond to stressors differently. The basic elements of the physiological stress response, such as the hormones, are present at very early stages of development, and the system appears functional around hatching or soon thereafter. Transitional stages such as the onset of feeding by mouth, metamorphosis, or smoltification and reproduction appear very sensitive to stressors in regard to the increased magnitude of their physiological response and decreased tolerance limits (Figure 3).

Ecological Consequences

Exposure to acute stressors reduces the fish's capacity to resist other immediate threats (Figure 3). Longer-term or repeated exposure to relatively brief stressors depresses the capacity of fish during the time they

Figure 3 Top panel: Conceptualization of the performance capacity of a fish's necessary life functions that are determined genetically and limited by the environment and negatively affected by stress. The length of each arrow (vector) goes from zero in the center to some level of performance at the point (Hb = hemoglobin). Bottom panel: Cartoon representing the performance capacity of a fish as it changes through time, showing a smaller capacity to resist stress during transitional stages.

are adapting to carry on other necessary life functions. The fish will have less energy to channel into anabolic processes such as growth, development, and reproduction.

It is likely that longer-term stress can change a fish's developmental trajectory and thereby alter its life history strategy. For example, fish that are stressed during certain stages of reproductive maturation may change their spawning strategy. Depending on species of fish and the nature of the stressor, spawning could be accelerated, delayed, or totally inhibited. Stress experienced by females can lead to lower egg quality and subsequent progeny fitness.

While general disturbances and deteriorated water quality can cause a stress response, negative social interactions and low hierarchical status also result in a similar response. Fish of low social rank grow less well and tend to have reduced chances of survival. Submissive fish are stressed by aggressive displays, have activated HPI axes, and suffer its maladaptive consequences.

Temperature is one of the most important environmental controlling factors for fish because the fish are cold-blooded. The rates of biochemical reactions that drive physiological processes are directly dependent on the temperature of the water; in general, for each 10°C increase in temperature, the rates of biological reactions double or triple. Temperature is thus a key variable regarding how fish respond to a stressor, both physiologically and ecologically.

How fish interact with pathogens and parasites is also affected by stress. Stress can increase both the infection rate and pathogenicity of a microorganism.

Introduction and Background

Postdisaster Coping

Postdisaster Effects on Children

Postdisaster Physical Symptoms

Postdisaster Effects on Emergency and Medical Personnel

Assessing Traumatic Exposure Severity and Symptoms

Introduction and Background

Flooding remains the most common catastrophe worldwide and accounts for an estimated 40% of all natural disasters and 26% of disaster-related deaths. Flash flooding kills more people in the United States than any other natural disaster, accounting for approximately 200 fatalities per year. Flash floods can occur within several seconds to several hours, with little warning and are deadly because they produce rapid rises in water levels and have devastating flow velocities. Several factors can contribute to flash flooding including rainfall intensity, rainfall duration, surface conditions, topography, and slope of the receiving basin. Urban areas are susceptible to flash floods because a high percentage of the surface area is composed of impervious streets, roofs, and parking lots where runoff occurs very rapidly. Mountainous areas also are susceptible to flash floods, as steep topography may funnel runoff into a narrow canyon. Floodwaters accelerated by steep stream slopes can cause the floodwave to move downstream too fast to allow escape, resulting in many deaths. One example of a deadly flash flood occurred after 37.5 cm of rain in 5 h from slow-moving thunderstorms killed 237 people in Rapid City, South Dakota, in 1972.

Floods can occur unexpectedly after excessive rainfall, tropical storms, hurricanes, or failing dams or levees. Deluges of heavy rains can quickly fill narrow ravines, mountain canyons, dry stream beds, or streets in a downriver community. Powerful torrents of water can roll boulders, tear out trees, destroy buildings and bridges, scour out new channels, trigger catastrophic mud slides, sweep away vehicles and houses, drown unsuspecting campers or residents, destroy property, kill or injure friends or family members,

cause homelessness, spread disease, deplete financial resources, and cause emotional and psychological symptoms. Indeed, floods are major disasters and the Federal Emergency Management Agency (FEMA) has warned people to consider these facts:

- Most flood-related deaths are due to flash floods,
- 50% of all flash-flood fatalities are vehicle related. Individuals should not drive through floodwaters,
- 90% of those who die in hurricanes drown. People should heed the warnings and evacuate areas where flooding from storm surges has been predicted,
- Most homeowners' insurance policies do not cover floodwater damage. Flood insurance can be purchased through FEMA's National Flood Insurance Program.

Flooding can also take place from storm surges caused by major hurricanes and are unquestionably the most dangerous parts of hurricanes. Pounding waves create very hazardous flood currents and depths of water that can be greater than 60 m, depending upon the distance of water and the velocity of the wind. Nine out of 10 hurricane fatalities are caused by storm surges. Worst-case scenarios occur when storm surges occur concurrently with high tides. Stream flooding is also much worse inland during storm surges because of backwater effects. In September 1900, the hurricane and storm surge at Galveston, Texas, killed nearly 8000 people, making it the worst natural disaster in the nation's history.

Floods seem to have become more severe and commonplace in recent years. Within the boundaries of the United States, there have been many severe floods. One of the most significant of these was the Great Mississippi Flood of 1927. Rains began in the summer of 1926 and by May of 1927 the Mississippi River had flooded and was 97 km wide below Memphis, Tennessee, and flooded 109 km² in six states: Arkansas, Illinois, Kentucky, Louisiana, Mississippi, and Tennessee. There were 246 people killed in seven states and damages exceeded \$650 million.

The floods of 1993 were also one of the greatest natural disasters ever to hit the United States. Major flooding primarily affected the Mississippi and Missouri rivers and extended into 150 major rivers and tributaries across nine states: North Dakota, South Dakota, Nebraska, Kansas, Minnesota, Iowa, Missouri, Wisconsin, and Illinois. Hundreds of levees failed and 600 river points were above flood stage at the same time. Fifty people were killed and damages approached \$15 billion.

When tropical storm Alberto lingered over the Florida Panhandle on 3 July 1994, the ensuing rains continued until Georgia's flood of the century eventually devastated its central and southwest portions, killed 32 people, displaced 70 000 people, flooded 1214 km² of croplands, caused crop damage of \$100 million, and a total monetary damage exceeding \$500 million.

Two devastating floods inundated much of northern California in January 1995. Three different hurricanes struck the Caribbean and the United States Atlantic Coast in late summer and fall of 1996; Bertha struck in July, Fran in September, and then Hortense washed away southwestern Puerto Rico. From the early months of 1997, unprecedented floods affected eastern, mid-western, and northern United States, particularly devastating communities bordering the Red River which flooded the Minnesota and North Dakota border and continued into Canada in April 1997.

With the onset of El Niño, 1998 became an unusually severe year for flooding. The Pacific Coast was devastated by rain, rising rivers, ocean swells, and killer mud slides in January and February followed by significant flooding in the southeast and Midwest from February until June. Downpours, high ocean swells, and flooding rivers struck the West Coast and the Southeast Coast of the United States with a fury in early February 1998. Southern California was inflicted with the worst wind and rain storms in 5 years. Rain soaked hills and dikes began giving way, causing more flooding and destruction of homes and property.

While blizzards in the Upper Midwest paralyzed highways, roads, and air traffic, rain brought 30–50 cm of rainfall across the south during early March, 1998. The community of Elba, Alabama evacuated 2000 of its 4000 residents when a levee broke and killed two children from torrents of water roaring through the town without warning. Fierce thunderstorms swamped parts of seven states in the northeast. Flooding was so extensive that it required helicopter rescues. Vermont's Mad river, usually docile in summertime, lived up to its name when it jumped the banks to wash out roads and destroy homes, and drove campers in Vermont to higher ground.

On 24 August 1998, flash floods from tropical storm Charlie struck Del Rio, Texas on the Mexico–Texas border. Within the first few days, it was known that 15 people lost their lives although rescuers were continuing to look for missing persons during the following week. South Texas continued to be a target during mid-October as 37–45 cm of rain over a period of several days flooded the Guadalupe and Colorado Rivers, causing the deaths of 24 people.

The Gulf Coast was also stricken by flooding from hurricane Georges which first struck Puerto Rico on

21 September 1998, and devastated the Dominican Republic. It swept across the Caribbean, the eastern coast of Cuba, the Florida Keys, and continued northward through the Gulf of Mexico until its center crossed the coast at Gulfport and Biloxi, Mississippi, 8 days later. Storm surges and flooding caused extensive damage and drove 1.5 million Gulf Coast residents from their homes. In Mobile, Alabama, a 2.7 m storm surge from Mobile Bay sent chest-deep water into many neighborhoods so that more than 300 people had to be evacuated.

In 1998, the worst flooding to hit Central America began on 27 October when hurricane Mitch stalled over the isthmus of Central America. Its 180 mph winds, accompanied by 62 cm of rain over a 6-hour period, first devastated the Island of Guanaja near the coast of Honduras. In 2 days, torrential rain immobilized the Honduran Capital of Tegucigalpa, then moved inland where rainfall estimated to be 63–125 cm caused flooding and mud slides that wiped out complete villages in the mountains of Honduras and Nicaragua. On 30 October 1998, the rim of the Nicaraguan Volcano Casitas burst, releasing a deadly torrent of water and mud which destroyed the villages of Rolando Rodriguez and Posoltega as most of its residents and several thousand others in Nicaragua, were killed. Virtually all of Honduras, from the lowland marshes on the Atlantic coast to the mountains, hills, and plateaus of the interior, along with most of the highways, tens of bridges, and 70% of the national agriculture in Honduras, was destroyed. President, Carlos Flores Facusse, announced: "There are corpses everywhere from victims of landslides or floodwaters. The floods and landslides erased from the map many villages and households as well as whole neighborhoods of cities. We have before us a panorama of death, desolation, and ruin throughout the national territory." The number of dead in Honduras, Nicaragua, El Salvador, Guatemala, Costa Rica, Belize, and Mexico was estimated at 10 000 with 13 225 people missing, four million people homeless, and very little clean water, food, and medicine.

When hurricane Stan struck Central America on 5 October 2005 it brought several days of rain and caused major flooding which impacted 1000 Central American communities which were covered partially or completely by water and mud. Along the Southern Coast and western highlands of Guatemala flooding and landslides caused loss of life, injury, and displaced persons as well as damage to housing and infrastructure in 251 of 331 municipalities in 15 of the country's 22 departments. There were over 900 landslides and considerable damage to a high proportion of roads and bridges. In the highland and south-western departments of Solola and San Marcos,

entire villages were swept away by landslides, with significant loss of life. One village was completely buried under tons of dirt and declared a Mayan mass grave site.

When category 3 hurricane Katrina struck the gulf states of Louisiana and Mississippi on 28 August 2005 there was flooding both from storm surges and heavy rains. The storm surge surpassed 6 m and caused major property destruction. The subsequent flooding of the City of New Orleans was unexpected and particularly devastating. Although hundreds of thousands of residents had left the danger zone prior to 29 August, there were yet thousands more who either refused to evacuate or were unable to leave. As Lake Pontchartrain rose to unprecedented heights, water began pouring into the city through broken levees. Over the next 2 days, the gradual rising water levels drowned the unfortunate who could not escape or forced them to their attics and rooftops.

On 4 September 2005, the Mayor of New Orleans speculated to reporters that the death toll might rise into the thousands after the clean-up was completed. By early November the number of confirmed fatalities in Louisiana reached a toll of 1056, a lower figure than previously estimated. Some fatalities were caused by self-destructive behaviors or violence, including one death at the Superdome evacuation site from a drug overdose and another from suicide. At least seven homicide victims were found in the city according to the medical examiner.

In early October 2005, heavy rain struck the eastern seaboard due to tropical storm Tammy and heavy rains and flooding which impacted five states and created enormous stress, according to the following time-table:

- Sunday, 9 October – Prolonged, heavy rain and flooding from North Carolina to New Hampshire. Hundreds of people evacuated, power lost, dams weakened and roads impassable. At least four people died, including two killed in New Hampshire when a car drove off a washed-out bridge into floodwaters. New Hampshire's Governor John Lynch declared a state of emergency and called in 500 National Guard for assistance.
- Monday, 10 October – At least 10 people dead and about six unaccounted for, including a couple whose house was washed away by a surge of water over Warren Lake dam in Alstead, New Hampshire.
- Tuesday, 11 October – Rescue crews and police dogs searched rivers and woods for people missing in New Hampshire after the weekend flooding. John Lynch said the floods are the worst the state had experienced in a quarter of a century.
- Thursday, 13 October – Steady rain fell around the saturated northeast, swamping roads, stalling airline passengers, and sending streams and rivers over their banks. Flood warnings covered parts of Connecticut, New York, and New Jersey.
- Friday, 14 October – Toilets backed up with sewage, military trucks plowed through headlight-high water to rescue people, and swans glided down the streets as rain fell for an eighth straight day around the waterlogged northeast. Overflowing lakes and streams forced hundreds of people from their homes, tens of thousands of sandbags were handed out in New Hampshire and flood warnings covered parts of New Jersey, New York, and Connecticut.
- Saturday, 15 October – The death toll from a week of driving rain and swelling floods across the Northeast rose to 11 after a 75-year-old Connecticut man was swept away by rushing water at a campground. Flooding also shut down major highways and forced hundreds to evacuate their homes. Massachusetts Governor Mitt Romney declared a state of emergency, following the lead of New Jersey. Flood warnings were in effect for New Jersey, New Hampshire, Connecticut, Massachusetts, Rhode Island, and southern New York.
- Sunday, 16 October – In Connecticut, the body of a woman who fell into the rapids of the Natchaug River in Chaplin was found.
- Tuesday–Saturday, 18–22 October – Taunton, Massachusetts. Population 50 000. Residents prepared for the worst after the 173-year-old, 3.6 m high Whittenton pond dam on the rain-swollen Mill river deteriorated, threatening a wall of water up to 1.8 m deep. Schools and businesses closed and thousands of residents were unable to return home as a weakened timber dam threatened to give way and spill a surge of water into downtown Taunton, Massachusetts. Over the next 4 days there was continuing heavy rain. About 2000 residents were evacuated and workers pumped millions of liters of water from the rain-swollen lake above the dam and begin shoring up the battered structure ahead of the new round of heavy rain that was forecast. Working in the rain, crews finished building a new rock dam and tore down the old wooden one that had buckled after a week of heavy downpours.

Postdisaster Coping

How do survivors cope with impending disasters related to rapidly rising water or flash floods? They have been observed to traverse through five psychological and emotional stress-related phases as follows.

Immediate Coping – Alarm and Outcry

In some cases victims become confused and overwhelmed by fear. However, most survivors respond to the danger with little or no expectation of personal risk, often with heroic efforts, clear thinking, and physical endurance. There are also those who refuse to believe the seriousness of the danger.

Early Adaptation – the Disbelief and Denial Response

Incredulity in the face of an extraordinary event should be perceived as normal, even potentially life-saving. But those who refuse to believe they will ever be overcome by life threatening circumstances can be at risk.

In some cases disbelief or denial can be a fatal response when individuals go too far and will not acknowledge they are in mortal danger. This attitude of omnipotence has been called the delusion of personal invulnerability. There are many examples throughout history. When the dikes broke, and 1835 people were drowned in The Netherlands in the early 1900s, many perished because they did not listen to those who warned of the danger. In somewhat similar circumstances, as the Rio Grande began to flood near Eagle Pass, Texas and Piedras Negras, Mexico in June 1954, warnings were issued for 36 h that a record crest was sweeping down the river. Nevertheless people refused to comprehend the danger and 130 persons were needlessly drowned.

Ideally, individuals will respond during this phase in a dramatic way to save lives. A very recent example occurred in Taunton, Massachusetts on 18 October 2005 when residents feared for the worst after the wooden Whittenton pond dam on the rain-swollen Mill River deteriorated and threatened to collapse (see earlier).

The fact that most survivors in the middle of a disaster are somewhat numb to the reality that they could be killed helps them contend with incredible circumstances as they organize themselves and other survivors in adaptive and innovative ways. Even after the disaster's force diminishes, survivors are likely to maintain an attitude of disbelief for a time until they begin to resume normal activities. In some cases, the demands on rescue workers and other helpers are exceedingly great during this time and the risk of developing significant physical and emotional symptoms is high. Reports from New Orleans' Methodist Hospital after hurricane Katrina had flooded New Orleans indicated that the medical staff worked unendingly in horrendous conditions and some succumbed to dehydration and exhaustion. Patients requiring ventilators were kept alive with hand-powered resuscitation

bags. When the first floor of the hospital flooded the dead were stacked in a second floor operating room. Other hospitals reported even more dire conditions and in some cases the hospital staff were unable to evacuate the severely ill and they did not survive.

Mid-Phase Adaptation – Intrusions

The middle phase is marked by intrusive recollections alternating with periods of denial and numbing as survivors begin to remember and relive their experiences in the form of intrusive thoughts, emotions, and dreams several days or weeks later. Their intrusive symptoms may be intensified when survivors finally realize they may have lost lives, health, or property. This phase may be prolonged or delayed when the work of recovery, reconstruction, or self-preservation becomes all consuming and there may also be delayed resolution by the use of alcohol or drugs.

Survivors often contend with a variety of other stresses at this time including possible injuries, losses, role changes, displacement, cleaning up, repairing property damage, moving into temporary or even new housing, and preparing lengthy health, recovery assistance, and insurance claims. Thus, posttrauma symptoms are related not only to the disaster itself but other related difficulties, which has been called the dripping faucet syndrome. Taken individually, many small stresses seem minor but when taken collectively they can push a person to the edge and cause irritability, withdrawal from relationships, or loss of pleasure in activities.

Disaster workers subjected to prolonged or highly intensive exposure to the disaster tend to remain emotionally numb until the enormity of the disaster finally sinks in. Not until then do they develop sleep disturbances and nightmares but these are frequently resolved within 4–6 weeks.

Late Phase Adaptation – Anger and Physical Symptoms

After a period of time (from 1 to 3 months) survivors are more prone to experience negative and hostile reactions. There is a marked decrease in tolerance, an increase in complaining, a loss of humor, and mistrust of others. This becomes a problem for those trying to help victims of trauma and for the victims themselves, who keep others at a distance. Couples may become more easily aggressive and prone to violent outbursts. During this phase there is also a marked increase in physical complaints including headaches, nausea, diarrhea, vomiting, muscle aches, chest pain, restlessness, tremors, sweating, and general fatigue. These symptoms may also be associated

with secondary victimization befalling those who are exploited by shysters, neglected by thoughtless people, and mistreated by dehumanizing agencies.

Resolution or Symptom Development

Finally, survivors either resolve their posttraumatic symptoms, develop recurring difficulties related to unresolved past stresses, or become victims of prolonged or worsening disorders associated with unresolved guilt, preexisting anxiety or depression, prior traumatization, drug or alcohol addiction, and organic syndromes. New symptoms may develop or prior difficulties may worsen including flashbacks, depression, obsessive-compulsive symptoms, panic attacks, nightmares, sleeplessness, interpersonal alienation, and emotional outbursts alternating with detachment. For some victims, these symptoms may extend indefinitely in the form of a chronic emotional or physical disorder requiring treatment.

Postdisaster Effects on Children

Children are vulnerable to all of the typical responses and symptoms following disasters and need special attention in order to prevent longstanding difficulties. Unfortunately, adults are not always aware of the full impact of traumatic stress on children nor do they always help them resolve their frightening dreams and memories. Most children, especially younger ones, become very fearful of being alone, overdependent, and sometimes clinging. They may also develop strong phobias, nightmares, night terrors, and regression to a previous level of function, including thumb sucking or bed wetting in younger children. Additional symptoms include clinging to parents, reluctance to go to bed, nightmares, fantasies that the disaster never happened, crying and screaming, withdrawal and immobility, refusal to attend school, school problems, inability to concentrate, and being poorly understood by parents and teachers.

Early intervention is particularly important for children. Parents need to recognize that withdrawal, fear, and overdependency will improve with time. Special care should be paid to helping the children resume normal daily routines within a safe and secure environment. Watching television programs about the flood can be helpful if parents are there to talk about what happened and reassure that being afraid is normal. Supervised trauma-related play can help children resolve their fears. They should be reassured with explanations like: "That hurricane is not a monster who took away children's toys and hurt people. The 'eye' will not seek children out or return again."

Postdisaster Physical Symptoms

Disaster survivors not uncommonly have physical complaints which often bring them to their doctor's offices. Following sudden disasters, many of the symptoms are associated with prolonged autonomic nervous system over-reactivity. Palpitations, tightness in the chest, shortness of breath, and feelings of dread may accompany intrusive memories. Headaches and gastrointestinal complaints are not uncommon. While survivors may have physical problems they often do not seek medical help. Researchers have found that only 40% of those reporting physical symptoms after a disaster consulted their doctors while 34% sought help from family members or friends. Most of them, 66%, sought medical help within 4 months while the remaining 33% waited until after 4 months to visit their physicians.

Survivors may also suffer from health problems indirectly linked to the disaster. For example, following the Iowa floods in the early summer of 1993, the national Centers for Disease Control (CDC) conducted a public health investigation. The CDC researchers discovered that survivors in seven Iowan counties had been hospitalized for flood-related illnesses or injuries, including carbon monoxide poisoning, hypothermia, electrocution, wound infections, and exacerbations of chronic illnesses.

Sometimes there are reports of unusual and long-term health problems. Investigators from the New York State Department of Health discovered some unusual health problems following a flood disaster in western New York in 1974. Within a population of 100 000 people exposed to flooding in three river valleys, scientists found a regional rise in spontaneous abortions as well as an increased incidence of leukemias and lymphomas of 4 years' duration, resulting in an excess of 30–35 malignancies. The reasons are not yet entirely clear.

After the flooding of New Orleans began on 29 August 2005, there was concern about a potential outbreak of serious health problems. Flood waters remained at high levels, over some roof tops, for a number of weeks and became toxic and a breeding area for bacteria. In addition to dehydration and food poisoning, New Orleans flood survivors were also at risk to contract hepatitis A, cholera, and typhoid fever, because of contaminated food and drinking water. Survivors also faced longer-term health risks due to prolonged exposure to the petrochemical tainted flood waters and mosquito-borne diseases such as yellow fever, malaria and West Nile Virus. *Escherichia coli* was detected in the water supply within a few days and at least five people died from bacterial infections caused by *Vibrio vulnificus* bacteria in the

toxic waters. Other sources of contaminations included dead bodies lying in city streets and floating in still-flooded sections, causing an advanced state of decomposition of many corpses, some of which were left in the water or sun for days before being collected.

Medical assistance began in earnest within 3 days when an emergency triage center was set up at the regional airport at New Orleans. Helicopters and ambulances brought in the weak, elderly, sick, and injured and makeshift gurneys were used to transport persons from the flight line to a temporary hospital set up in the terminal. The captain in charge described the site as organized chaos but the emergency medical staff assembled from around the country kept pace and were able to handle anything from bruises to critical cases requiring ventilators. They triaged the seriously ill and injured to medical centers in the surrounding states and within 72 h had triaged up to 5000 people.

The potential health problems from flooding affected the residents of the city who had been evacuated. They were unable to return to their homes because of the length of time necessary for the Army Corps of Engineers to drain the flood waters. They managed to accomplish the task within 1 month but parts of the city re-flooded when hurricane Rita struck on 24 September. Many buildings that had withstood the initial storm and the direct force of the flooding were damaged beyond repair by the deleterious effect of long immersion and the rapid propagation of mold.

Hundreds of thousands of New Orleans residents that were displaced by the flooding lost their homes completely and the subsequent emotional effects will not be known for some time.

Postdisaster Effects on Emergency and Medical Personnel

Emergency medical technicians, law enforcement personnel, military medics or corpsmen, fire fighters, emergency room workers, physicians, intensive care nurses, and other crisis workers are exposed routinely to persons who are severely injured, killed, deathly ill, or have expired unexpectedly. These helpers usually adapt to their stress by becoming emotionally numb and detached from their feelings. As a result they can develop a pattern of maintaining emotional distance from people while preferring to throw themselves into their work. This accumulated exposure to traumatic events eventually causes posttraumatic symptoms: emotional detachment, sleep disturbance, irritability, marital problems, alcohol abuse, physiological symptoms, and an addiction to repetitive

stress. Helpers (health professionals, mental health workers, ministers, and even business executives) can feel used up. They eventually find it difficult, if not impossible, to meet the emotional and communication needs of their wives and children. They even ignore their own personal needs for rest and recreation as they often turn to work for gratification rather than their families. Eventually this leads to burnout.

Helpers may find it emotionally stressful and experience intense feelings in response to listening to victims' stories about disasters, assault, sexual abuse, and violent trauma. Those with little experience may even feel confused and even ashamed while empathically taking on the victim's emotional distress. The listener's experience may lead to symptoms of depression, bad dreams, irritability, excessive drinking, and other distressing difficulties caused by a process called vicarious traumatization (VT).

Assessing Traumatic Exposure Severity and Symptoms

The severity of symptoms, should they persist, often are frequently directly correlated with the enormity of the traumatic experience/loss or accumulation of prior unresolved traumatic experiences. Survivors may have experienced a seemingly unending series of stressors. For example, they may have suffered damage or destruction to their homes or personal belongings. They may have witnessed violence, injury, deaths of other victims, and they may have lost loved ones and pets.

When survivors fail to talk openly about the event(s); if they have been separated from family members; if they lack emotional support from friends or family members, the emotional aftermath is more severe. They are at risk to experience many or all of the following symptoms: flashbacks, sleep disorder, anxiety attacks, recurring nightmares or dreams, problems with concentration and memory, intrusive recollections, irritability, emotional outbursts alternating with periods of emotional numbing, misusing drugs or alcohol, and interpersonal conflicts. Clearly, individuals who are experiencing these symptoms should seek the help of an experienced trauma therapist. A successful resolution is possible when survivors find relief from their symptoms and discover new or broadened meaning in their lives.

Effect of Stress on Food Intake

Effect of Food Composition and Intake on the Ability to Cope with Stress

Glossary

<i>Dietary restraint</i>	The tendency to control food intake consciously in order to prevent weight gain or promote weight loss.
<i>Dieting</i>	A behavior designed to bring about weight loss that demands a relatively severe degree of food restriction.
<i>5-Hydroxy-tryptamine (serotonin)</i>	A neurotransmitter, present in the brain, that is involved in controlling many different behaviors, including food intake, mood, motor output, learning, sleep, circadian pattern, aggression, and sexual behavior.
<i>Macronutrients</i>	Components of food, including carbohydrate, fat, and protein.

Satiety

The feeling of fullness that increases as food is ingested and that increases the drive to stop eating.

Tryptophan

An amino acid that forms one of the essential components of protein.

Effect of Stress on Food Intake

Under a variety of stressful conditions, food intake is altered in both animals and humans. However, different stressors seem to have different effects, with some resulting in an increase and some in a decrease in food intake. In human studies, some subjects appear to be nonresponders to stress, whereas of the responders, some markedly reduce their intake (stress fasters) while others increase their intake (stress eaters). Stress-induced eating is of particular interest because of the role it may play in contributing to obesity. Much over-eating behavior is reported to be stress related, and some obese subjects report a decrease in anxiety after eating.

In everyday life there are a number of specific stressors that have an impact on food intake, particularly in women. Since the 1960s, Western society has placed increasing demands on the population, particularly women, to be slim and to aspire to an ideal of thinness. There has been an associated increase in

body image dissatisfaction, particularly among young women. This has also coincided with a dramatic increase in the prevalence of dieting and of eating disorders such as anorexia and bulimia nervosa. The prevalence of eating disorders seems to be in direct proportion to the prevalence of dieting behavior in a given community, and longitudinal studies of young adults suggest that the risk of developing an eating disorder is significantly higher among dieters than non-dieters. Indeed, most of those suffering from an eating disorder report that their eating problem started as normal dieting that then got out of control.

Low self-esteem is an additional factor associated with dieting, body image dissatisfaction, and alterations in eating pattern, although it is difficult to know whether this is a cause or an effect. Subjectively, low mood and low self-esteem are often reported to be contributing factors to unwelcome weight gain. Experimentally induced stress or dysphoria in volunteers causes an increased food intake in some individuals. This effect occurs particularly in those subjects who are dieting or are restrained eaters, but not in those who are not restricting their food intake. Interestingly, subjects who binge eat often report that this occurs in response to stress or dysphoria and, at least initially, binges seem to relieve anxiety.

Dieting and dietary restraint are intimately bound up with mood and self-esteem. Subjects who restrict their food intake to lose weight record ratings of happiness that are directly related to weight loss or weight gain. In contrast, subjects who are not restricting intake report that weight change has little impact on ratings of happiness. Feedback to subjects about weight change will therefore alter mood, which in turn can affect food intake and weight. In a study where subjects were weighed regularly but the results were fed back to them as consistently heavier than their true weight, restrained eaters reported more mood changes than nonrestrained eaters in response to the feedback, including anxiety, depression, and low self-esteem. Interestingly, these restrained eaters, who experienced lowered mood, then ate more in a subsequent test meal.

Thus, there is growing evidence that stress can alter food intake. However, there is debate about how this effect is mediated. Stressful events can alter a number of different biological variables, which in turn could affect food intake. It has been hypothesized that stress-induced increases in food intake are mediated by endogenous opiates. Stress increases the release of β -endorphin, a naturally occurring opiate that increases food intake, but also reduces the perception of pain and the anxiety associated with stress.

An alternative is that these effects are mediated by the neurotransmitter 5-hydroxytryptamine (5-HT). 5-HT has attracted great interest because its function

seems to be altered in disorders such as depression, which are known to be closely associated with the occurrence of stressful life events, and in eating disorders such as bulimia nervosa. In addition, altering 5-HT function (e.g., by using medication) has a profound effect on eating behavior. In human and animal studies, interventions that increase 5-HT function reduce food intake; conversely, reducing 5-HT function increases food intake.

Could levels of 5-HT be altered by stress? Stress increases the level of a naturally occurring hormone, cortisol. When this occurs, 5-HT function is reduced. Reduced 5-HT function would be expected to lead to increased food intake, and experimental work suggests that this increase would occur particularly in carbohydrate intake, rather than protein. Interestingly, this alteration in the balance of macronutrients could itself affect 5-HT function. This is discussed in more detail in the next section.

Effect of Food Composition and Intake on the Ability to Cope with Stress

Research on the biological and psychological effects of varying food intake has focused on two main areas. First, there has been interest in the behavioral effects of dieting. Second, there has been interest in the effects of dieting on biological parameters, some of which may affect the ability to cope with stress. Research in the latter area has focused on the effects of dieting on the neurotransmitter 5-HT. 5-HT is biologically unusual in that the rate of its synthesis is entirely dependent on the supply of its essential amino acid precursor, tryptophan, in food. Furthermore, the availability of tryptophan to the brain depends on the balance of macronutrients (carbohydrate, protein, and fat).

Dieting is a very common behavior in Western cultures. Approximately 25% of men and 40% of women in the United States report that they are currently trying to lose weight. Dieting seems to be particularly common among adolescent girls, but the rates are higher at all ages in women compared with men.

Behavioral Effects of Dieting

The first direct evidence on the behavioral effects of food restriction came from a study of World War II conscientious objectors who were placed on a 24-week semistarvation diet. The main findings were an increase in lethargy, tiredness, depression, and irritability and a lowering of energy. In contrast, other studies using less extreme dietary restriction have found less dramatic changes in mood.

Several studies have shown that dieters perform less well on cognitive tasks. Dieting impairs sustained attention and short-term recall and results in slower

reaction times. Nondieters with high levels of restraint over eating showed intermediate cognitive performance between dieters and low restraint nondieters. Impairments in cognitive functioning, such as impaired vigilance, have also been noted among subjects with bulimia nervosa and anorexia nervosa, probably due to restricted eating.

Dieting itself affects eating behavior. In a series of well-replicated studies, Polivy and Herman showed that dieters failed to compensate for a modest calorie loading by decreasing their caloric intake at the next meal. They actually ate more after the preload than after no preload; they counterregulated rather than showing the normal compensatory regulation seen in the controls. It has been widely argued that counterregulation is a result of the preload causing disinhibition and abandoning of dietary restraint in the dieter. This cognitive explanation is supported by the finding that dieters also counterregulate when they perceive the preload as high in calories, regardless of the actual calorie content.

Severe dietary restriction in normal controls can result in binge eating. The World War II study of conscientious objectors described earlier also investigated the effects of refeeding. The men returned to their normal weights after the study but exhibited a persistent tendency to binge eat. This type of behavior had not occurred prior to the study. Healthy volunteer studies during short-term calorie-controlled diets show that subjects have increased preoccupation with thoughts of food, urges to eat more frequently, and feelings of being out of control with their eating. Rates of postwar binge eating in World War II combat veterans and prisoners of war show that binge eating is significantly more prevalent in veterans who lost large amounts of weight during their captivity.

Thus, dietary restriction and normal dieting have significant effects on behaviors such as food intake, mood, and cognitive functioning. There has been debate, however, about how these effects are mediated. One possibility is that dieting alters 5-HT function, discussed next.

Dieting and 5-HT

The rate of synthesis of 5-HT in the brain is critically dependent on the amount of its precursor, tryptophan, which is able to enter the brain. Tryptophan is available solely from the diet, and its availability in the brain can be critically affected by alterations in food intake, particularly in the balance of macronutrients. Tryptophan competes for entry to the brain across the blood-brain barrier with other amino acids (components of protein). Any change in food intake that alters this ratio of tryptophan to other amino acids will directly affect the amount of 5-HT synthesized.

Studies of the effects of a standard 3 week, 1000 kcal diet have shown that the diet results in a lowering of tryptophan in the plasma (blood). The key question is whether this affects 5-HT function itself. Studies using a variety of challenge tests for different aspects of 5-HT function show that it does, although the effect is significant only in women. It seems that female dieters can compensate to some extent for the reduction in 5-HT synthesis induced by dieting, but it is likely that dieting results in a reduction in 5-HT function. Because this effect is gender specific, women may be biologically more vulnerable to the effects of dieting on 5-HT function.

What might be the consequences of this lowered 5-HT function after dieting? First, decreased 5-HT function will reduce satiety and increase the drive to eat. This may be one of the reasons why it is often reported that dieting is difficult to sustain. Some subjects who are dieting report craving carbohydrate or even bingeing on high-carbohydrate, low-protein foods. Wurtman and colleagues have proposed that this craving may be explained by the fact that these foods increase 5-HT function indirectly. This occurs because a carbohydrate-rich meal causes secretion of the hormone insulin, increasing the ratio of tryptophan to other amino acids and an increase in the entry of tryptophan to the brain. The end result is an increase in the synthesis of 5-HT, which to some extent may correct the deficit induced by dieting.

It is also possible that the reduction in 5-HT function might affect mood. Experimental work using an artificial mixture of amino acids to temporarily lower 5-HT synthesis has shown that this can induce symptoms of depression, but only in women who have a strong previous history of depression. Animal and human work suggests that a key role of 5-HT is to promote resilience in the face of stressful circumstances. Failure of this system, thus reducing a person's ability to deal effectively with a stressful life event, may be one of the key factors contributing to the onset of depression. If dieting impairs 5-HT function directly, it may contribute to the onset of depression after a stressful life event. However, this may occur only in those people who have a vulnerability to depression because of their heredity or past history. Further research on the effects of dieting, particularly in people at risk of depression or eating problems, will need to be performed before this hypothesis can be confirmed.

Possible Hormonal Signals Involved in Mediating Nutritional Stress

Glossary

<i>Basal metabolic rate</i>	The rate of oxygen consumption, or calculated equivalent heat production, of an awake individual lying at rest who has had no food for at least 12 h.
<i>Gluconeogenesis</i>	The formation of glucose from non-carbohydrate sources such as lactate or fatty acids.
<i>Nutritional stress</i>	A physiological, environmental, or metabolic stress that is imposed on an organism to disrupt metabolic homeostasis, thus causing a neural and/or endocrine response.
<i>Orexigenic factor</i>	A factor that acts to increase appetite and stimulate food intake.

Introduction

Nutritional stress is, in some cases, an environmental stress and, in all cases, a metabolic stress. In particular cases, such as pregnancy and lactation, it could be construed that the nutritional demands of these states impose a physiological stress demanding increased food intake. In nonhuman species, nutritional stress occurs with a reduction in the availability of food or increased metabolic demand, but obesity is also associated with increased levels of stress hormones. In humans, a nutritional stress may be voluntarily imposed or due to psychogenic factors that have poorly defined etiology. The degree of impact varies among species depending on the type of metabolism of the organism (monogastric versus ruminant, for example) and also on the amount of body reserves of the organism.

Nutritional stress causes an alteration in the metabolic status of the animal and leads to altered concentrations of circulating metabolic substrates and metabolic hormones such as insulin and leptin. It is clear that blood-borne substances signal the metabolic status of the animal to the brain and that this leads to the alteration of hormonal output. These are responses of the organism to the stressor, but it is unlikely that a single factor that fulfils this signaling role. The neuroendocrine response to such a stress is probably the result of integrated effects of a composite of blood-borne substances. The gut may also

signal directly to the brain by a neural route and through the altered secretion of ghrelin to regulate brain function and hormonal status.

Nonhormonal Responses to Nutritional Stress

Stress due to undernutrition produces a catabolic state, typified by changes in the levels of various substances in the bloodstream. Changes in metabolic factors, however, can be influenced by other physiological stimuli, so variations in the concentrations of singular components do not often reflect metabolic state. For example, fat is metabolized during a fast to produce nonesterified fatty acids (NEFA) that are used to synthesize carbohydrates via gluconeogenesis. Accordingly, plasma NEFA levels are elevated during a fast. On the other hand, prolonged undernutrition decreases body fat, leading to reduced NEFA levels, and obese subjects have increased NEFA levels, due

to increased body fat. Thus, plasma NEFA concentrations are increased in both fasting and obese states. Other changes indicative of a catabolic state include reduced plasma insulin and leptin levels and increased plasma urea concentrations (due to the breakdown of muscle tissue in an effort to mobilize amino acids for the production of carbohydrates via gluconeogenesis). Chronic undernutrition (and a reduction in gluconeogenic substrates such as NEFA and amino acids) is typically associated with a reduction in plasma glucose concentrations. Plasma levels of these metabolic factors are a reflection of nutritional state (undernutrition versus obesity) and also the extent of catabolic stress (fasting versus prolonged undernutrition).

Hormonal Responses to Nutritional Stress

Endocrine changes occur during food deprivation or food restriction and the effects of fasting are summarized in [Table 1](#).

Table 1 Endocrine changes occur during food deprivation or food restriction^a

<i>Hormone</i>	<i>Change</i>	<i>Comments</i>
Small monogastric animals (e.g., laboratory rat)		
Catecholamines	↑	Reflects the output of adrenalin from the adrenal medulla; catecholamines are lipolytic, mobilizing fat stores in response to reduced energy substrate
Insulin	↓	Insulin facilitates the uptake of sugar from the bloodstream
Growth hormone	↓	Response is opposite to that seen in large animals and also opposite to the response seen in humans
Gonadotropins (LH and FSH)	↓	Fasting for a period of 1–2 days can prevent the preovulatory LH surge in rats
Gonadal steroids (estrogen, testosterone, progesterone)	↓	
Prolactin	↓	With extended period of undernutrition
ACTH	↑	
Cortisol	↑	
TSH	↓	
T ₃	↓	Through reduced conversion of T ₄ to T ₃
Nonhuman primates		
Insulin	↓	
Catecholamines	Not known	
Growth hormone	↑	
Gonadotropins (LH and FSH)	↓	LH is decreased, but there is a slower response in terms of FSH
Prolactin	Not known	
ACTH	Not known	
Cortisol	↑	
TSH	Not changed in the short term	
T ₃	↓	
Ruminants		
Catecholamines	Not known	
Growth hormone	↑	
Gonadotropins (LH and FSH)	↓	LH is decreased, but there is a slower response in terms of FSH
Prolactin	Not changed	
Adrenocorticotropin	Not known	
Cortisol	↑	Morning levels only

^aACTH, adrenocorticotrophic hormone; FSH, follicle stimulating hormone; LH, luteinizing hormone; T₃, triiodothyronine; T₄, thyroxine; TSH, thyroid stimulating hormone.

Nutritional Stress and the Hypothalamic-Pituitary-Adrenal Axis

General Considerations

The hypothalamic-pituitary-adrenal (HPA) axis is commonly activated by nutritional stress, which results in the increased secretion of glucocorticoids from the adrenal cortex. Most information to date has been derived from the laboratory rodent. The degree of activation of the HPA axis is dependent on a variety of factors, including:

- The species studied (monogastric small mammals such as rodents versus larger ruminant mammals such as sheep).
- The degree of intensity of undernutrition.
- The duration of undernutrition.
- The nutritional state of the animal prior to onset of catabolic state.
- The time of day; there is a diurnal pattern of glucocorticoid secretion.

Plasma glucocorticoids are elevated in states of undernutrition and in obese subjects, so both conditions might be regarded as stressors. The degree of change in body condition is an important factor. With undernutrition, the rapidity of change may also be a determinant of the stress response because animals can adapt over time to reduced energy stores. In obesity, the impact on the stress axis (glucocorticoid levels) depends on the obesity phenotype (where fat is distributed in the body).

There are species differences in the stress response to changing nutritional status and effects on plasma glucocorticoid levels are summarized in Table 2. It is important to note that the major glucocorticoid in rodents is corticosterone, whereas larger species including humans produce cortisol. Small monogastric mammals such as rodents exhibit robust activation of the HPA axis in response to fasting, but the same is not true for ruminants, in which digestion of nutrients is slower. Ruminants have a dynamic digestive system, with four stomach compartments (rumen, reticulum, omasum, and abomasum), which enables

them to digest their primary dietary component, cellulose. Ruminant digestion takes a considerable time, so there is a delayed response to fasting. Furthermore, ruminants stringently maintain blood glucose levels by the mobilization of NEFA from fat stores. Small animals have higher basal metabolic rates, which impacts fuel utility. Small animals (rodents) also have very low fat stores (approximately 10%) in comparison to larger species, including both sheep and humans (approximately 20%).

The Effect of Fasting versus Food Restriction on Hypothalamic-Pituitary-Adrenal Axis Activity

The effect of nutritional stress on the HPA axis is dependent on the duration and the intensity of undernutrition. Fasting is often used in the laboratory as a nutritional stressor, and in rodents plasma corticosterone levels are elevated within 24 h. In sheep, the response takes longer and cortisol secretion is increased 48–72 h after the commencement of fasting. In rodents, chronic food restriction (animals fed a 50% maintenance diet) for 4 weeks increases plasma levels of corticosterone, but basal cortisol levels are minimally changed in sheep made lean by long-term food restriction. There is a perturbation of the diurnal pattern of cortisol secretion in fasting sheep, with higher morning levels.

Pregnancy and Lactation

Pregnancy and lactation can be considered physiological conditions that induce nutritional stress by virtue of the high energy demands consigned to the mother. In small mammals, it has been calculated that the energy demands of lactation are four times greater than those of nonpregnant females. The high metabolic demands of lactation are met by profoundly increased food intake, driven by changes in appetite-regulating systems in the brain. Unlike other typical nutritional stressors, however, lactation is associated with hyporesponsivity of the HPA axis; neuroendocrine responses to stress are blunted in lactating animals. adrenocorticotrophic hormone (ACTH) and

Table 2 Species differences in glucocorticoid responses to nutritional stressors

	<i>Laboratory rodent</i>	<i>Sheep</i>	<i>Nonhuman primate</i>	<i>Human</i>
Fasting	↑ Corticosterone within 24–48 h	↑ Cortisol within 48–72 h	↑ Cortisol within 24 h	↑ Cortisol within 24 h
Food restriction	↑ Corticosterone	No change	Unknown	↑ Cortisol
Obesity	↑ Corticosterone in genetic models of obesity such as the fatty Zucker rat and the <i>ob/ob</i> mouse	No change in basal cortisol concentrations ↑ Cortisol response to stress	Unknown	↑ Cortisol (particularly in abdominal obesity)

cortisol levels are maintained during pregnancy, whereas corticotropin releasing hormone (CRH) levels are elevated due to peripheral synthesis and secretion by the placenta. This increase in CRH production is counteracted by increased circulating levels of CRH-binding protein (which sequesters CRH), thus preventing inappropriate secretion of ACTH. This phenomenon, however, occurs only in mammals that produce placental CRH.

Nutritional Stress and Negative Feedback Mechanisms of the Hypothalamic-Pituitary-Adrenal Axis

The HPA axis is tightly regulated by glucocorticoid (and mineralocorticoid) feedback to the hypothalamus and the anterior pituitary gland to regulate the secretion of hypophysiotropic hormones (CRH and arginine vasopressin, AVP) from the hypothalamus and ACTH from the pituitary corticotrophs. It has been hypothesized that abdominal obesity in humans and other species leads to dysfunction of the negative feedback actions of glucocorticoids, causing upregulation of the HPA axis and increased plasma levels of cortisol. In rodents, it has been hypothesized that decreased negative feedback actions within the brain actually precedes the obese state; animals susceptible to diet-induced obesity have decreased levels of glucocorticoid receptor mRNA within the hippocampus compared to diet-resistant animals.

Some work suggests that the sensitivity of the HPA axis to the negative feedback effects of glucocorticoids depends on carbohydrate ingestion. Adrenalectomized rodents suffer various abnormalities within the HPA axis, including increased expression of CRH mRNA in the paraventricular nucleus of the hypothalamus and decreased expression of CRH mRNA in the central nucleus of the amygdala. Interestingly, these perturbations in the adrenalectomized animal can be ameliorated by the ingestion of sucrose. Similarly, feeding animals a diet high in fat content also impacts on the HPA axis. For example, feeding rats a diet containing 20% fat (control diet, 4% fat) increases both basal and stress-induced secretion of ACTH and corticosterone. In contrast, feeding rats a diet very high (60%) in fat can decrease hormonal responses to stress. Thus, in animals, as in humans, the macronutrient dietary content impacts the reactivity of the HPA axis.

Nonadrenal Production of Glucocorticoids in Obesity

Peripheral tissues, other than the adrenal cortex, are able to produce glucocorticoids. This occurs by conversion of inert 11-keto steroids (11-dehydrocorticosterone in rodents and cortisone in humans) to active

11-hydroxy steroids (corticosterone in rodents and cortisol in humans). This process is regulated by the 11 β -hydroxysteroid dehydrogenase (11 β -HSD) enzymes; 11 β -HSD-1 catalyzes the synthesis of active 11-hydroxy steroids, and 11 β -HSD-2 catalyzes the synthesis of the inactive 11-keto steroids. The 11 β -HSD-1 enzyme is predominantly expressed in white adipose tissue, the liver, and the central nervous system (particularly the paraventricular nucleus of the hypothalamus and the hippocampus). In genetic models of obesity such as the *ob/ob* mice (a naturally occurring mutation in the gene that encodes leptin) and the fatty Zucker rat (a mutation in the gene that encodes the leptin receptor), the expression of 11 β -HSD-1 mRNA and 11 β -HSD-1 enzymatic activity is increased within adipose tissue, whereas expression is reduced in the liver. Furthermore, overexpressing 11 β -HSD-1 mRNA within the adipose tissue of transgenic mice specifically increases local concentrations of corticosterone. Such animals have an obese phenotype, but this is not associated with increased plasma levels of corticosterone.

The Role of the Hypothalamic-Pituitary-Adrenal Axis in the Predisposition to Obesity

In rodents, genetic obesity (the *ob/ob* mouse and the fatty Zucker rat) causes elevated concentrations of corticosterone. Adrenalectomy attenuates (or completely reverses) the obese phenotype in these animals. Furthermore, in nonmutated rodents, adrenalectomy reduces food intake, and corticosterone replacement restores normal feeding behavior. The stimulatory effect of glucocorticoids on food intake, however, cannot be displayed in an adrenal-intact rodent.

In rodents, mild pain induced by tail pinch initially increases food intake, but this effect is abolished by repeated experience; chronic exposure to tail pinch reduces food intake and body weight. Similarly, in rats repeated restraint stress reduces food intake and body weight, and this effect can be mimicked by chronic treatment with corticosterone. This decrease, however, is in comparison to rats fed *ad libitum*. In contrast, animals pair-fed to a similar (and lower) plane of nutrition tend to have lower body weights and reduced fat deposition compared to animals exposed to either repeated restraint stress or glucocorticoid treatment.

Neuronal Systems Underlying Endocrine Perturbations Induced by Nutritional Stress

There are numerous neuropeptides and neurotransmitters that are involved in both the regulation of

appetite and neuroendocrine functions. Within the hypothalamus, this involves a number of interconnected nuclei. The arcuate nucleus is essential to the regulation of food intake and body weight and produces a number of neuropeptides, including the appetite stimulators neuropeptide Y (NPY) and agouti-related protein (AGRP) as well as the appetite inhibitors α -melanocyte stimulating hormone (α -MSH; derived from the proopiomelanocortin, POMC, gene) and urocortin 2. Other regions of the hypothalamus involved in regulating food intake and neuroendocrine function include the paraventricular nucleus, which produces the appetite inhibitors CRH, urocortin 1, urocortin 2 and urocortin 3; the lateral hypothalamic area, which contains the appetite stimulators melanin-concentrating hormone (MCH) and the orexin; and the ventromedial hypothalamic nucleus. Various appetite-regulating peptides impact on the HPA axis and these are summarized in Table 3.

In addition to the hypothalamus, several nuclei in the brain stem also regulate feeding behavior and the HPA axis. Brain stem nuclei can regulate HPA function by ascending projections to the forebrain or via descending spinal projections to the adrenal gland. For example, noradrenergic input from the

locus ceruleus to the paraventricular nucleus of the hypothalamus is involved in the regulation of HPA function as well as food intake. In sheep and rats, various studies document the effects of nutritional stress on the expression of genes that encode appetite-regulating peptides. For example, in sheep made lean by chronic food restriction, the expression of genes encoding NPY, AGRP, and MCH is increased, indicative of increased hunger drive; these animals, however, have normal basal cortisol secretion. On the other hand, in fasted rodents, the expression of the same genes (NPY, AGRP, and MCH) is increased and there is activation of the HPA axis. Species differences in neuronal circuitry regulating the HPA axis may be relevant to the way that alteration in body weight affects the stress axis.

Possible Hormonal Signals Involved in Mediating Nutritional Stress

Various hormonal signals relay information about nutritional state to the appetite-regulating and neuroendocrine centers of the brain. Three hormones that play an important role are leptin, ghrelin, and insulin.

Leptin

Leptin is primarily produced by white fat tissue, and its plasma levels reflect the level of adiposity. In rodents, there is a tight negative correlation between the plasma levels of leptin and corticosterone. In rodents and sheep, the fasting-induced activation of the HPA axis is ameliorated by leptin treatment. Leptin also attenuates the ACTH and corticosterone responses to a physical stressor (hind-limb restraint) in rats. This suggests that leptin may in fact influence the neuroendocrine stress axis under conditions not associated with either nutritional or metabolic perturbations. The mechanisms by which leptin exerts such an effect are most likely to be centrally mediated. *In vitro* studies show that leptin can influence CRH secretion from isolated rat hypothalami but not ACTH secretion from cultured rat pituitary cells. A subpopulation of CRH-containing cells in the hypothalamus expresses the leptin receptor, allowing for direct action at this level of the HPA axis. Leptin receptors are also found in many cell types in the brain that provide afferents to the paraventricular nucleus, so there is likely to be relayed effects as well. Such cell types include those that produce NPY, MCH, and POMC.

Ghrelin

Ghrelin is primarily secreted from the stomach and has been shown to potently stimulate the secretion of

Table 3 The effect of hypothalamic appetite-regulating peptides on the HPA axis^a

	Neuropeptide	Effect on food intake	Effect on HPA axis activity
Arcuate nucleus	NPY	↑	↑
	AGRP	↑	↑

growth hormone. In some species, ghrelin also acts within the brain to stimulate food intake. Studies in sheep show that a preprandial rise in ghrelin levels stimulates a postprandial rise in growth hormone levels. Plasma levels of ghrelin fall postprandially and are increased by fasting or reduction in body weight; levels are lower in obese individuals. In addition to the stimulation of growth hormone, ghrelin activates the HPA axis, although not in all species. Ghrelin mRNA levels are increased after both physical (tail pinch) and nutritional (fasting) stress. Thus, ghrelin may be an additional factor involved in the regulation of the HPA axis under stressful stimuli. Ghrelin acts via the growth hormone secretagogue receptor, which is present in both the central nervous system and the pituitary gland. In rodents, the *in vivo* action of ghrelin on the HPA axis is exerted centrally, via cells such as those that produce NPY and AGRP in the arcuate nucleus. The orexin system in the lateral hypothalamus has also been linked to ghrelin-induced corticosterone secretion.

Insulin

The role of insulin in the regulation of food intake and neuroendocrine function is sometimes confused with the confounding effects of insulin-induced hypoglycemia. The latter increases food intake due to glucose deprivation, whereas in other circumstances insulin acts to decrease food intake. In rodents, diabetes causes increased basal concentrations of ACTH and corticosterone but reduced responsiveness to stress. Streptozotocin-induced diabetes impacts various neuronal systems, which in turn may influence the HPA axis. For example, streptozotocin-induced diabetes increases the concentration of norepinephrine within the paraventricular nucleus of the hypothalamus, and this parallels increasing levels of corticosterone. This effect is dependent on insulin concentrations because insulin replacement restores levels of norepinephrine within the paraventricular nucleus and the peripheral concentrations of corticosterone. Interestingly leptin treatment, in the absence of insulin

replacement, also corrects these streptozotocin-induced perturbations. In addition to effects on catecholaminergic systems, diabetes-associated changes in HPA axis function may be mediated via hypothalamic peptides such as NPY. In the rat, the arcuate nucleus contains insulin receptors and insulin decreases NPY mRNA expression in this region.

Endogenous Circadian Clocks
Physiological Correlates of Entrainment by Meals
Shift Work and Jet Lag
Conclusion

Glossary

<i>Circadian rhythm</i>	A cycle with a period of approximately 24 h.
<i>Entrainment</i>	A zeitgeber forcing its period and phase on a rhythm.
<i>Phase</i>	A point in the circadian cycle.
<i>Zeitgeber</i>	A periodic external cue that entrains circadian clocks.

Endogenous Circadian Clocks

In 1972, the neural substrate responsible for the generation and entrainment of circadian rhythms by light was identified. Lesions of this small structure, the suprachiasmatic nucleus (SCN) of the hypothalamus, appeared to abolish circadian rhythms in behavior and physiology. However, despite such lesions, rats were still able to anticipate one meal per day by increased activity, a rise in core temperature and serum corticosterone, and other physiological changes that occurred approximately 2–4 h prior to meal access. There is now compelling evidence that these functions are mediated by an endogenous circadian clock: (1) meal anticipation occurs only if the interval between meals is in the circadian range (~22–30 h), (2) anticipatory activity persists for several days when rats are food-deprived or the activity free runs (in some rats) if meals are presented outside the circadian range, and (3) phase shifts of meal-time result in transients, that is, gradual daily adjustments until the activity reentrains to the new meal time (see [Figure 1](#)). Despite many efforts, this feeding-entrained oscillator (FEO) has not yet been localized. Nevertheless, most mammals, as well as some inframammalian species, are now known to have the capacity to anticipate daily meals, and it would be surprising if humans lacked such a circadian

clock. It is well known that hunger sensations arise around the customary meal time. What has been difficult to explain from a purely homeostatic view is that the omission of a meal does not produce monotonically increasing feelings of hunger; instead, hunger subsides until the next customary meal time. However, this makes sense if hunger sensations are based in part on an internal timing signal and not entirely on an energy-deficit signal.

Physiological Correlates of Entrainment by Meals

Before addressing the potentially adverse effects of changes in meal time or meal omission, a brief summary of the main effects of feeding one meal per day on the rat's digestive physiology is in order. As mentioned earlier, serum corticosterone levels rise prior to expected meals. Corticosterone is both a metabolic and a stress hormone, and the brain has receptors for this steroid. Perhaps most surprising is the observation that disaccharidases (enzymes for digesting sugars) in the duodenum also increase before the meal is available. In addition, several aspects of liver function, cell division in the gastrointestinal tract, and intestinal motility become entrained to periodic meals. The increase in core temperature also may facilitate digestion. The general inference to be drawn from these observations is that the digestive physiology is not simply reactive to ingested nutrients but is capable of anticipating and preparing for meals, most likely under the influence of the circadian FEO. If the expected meal is displaced in time, these efforts are for naught and for several days these preparatory responses are out of synchrony with actual food consumption.

Shift Work and Jet Lag

Gastrointestinal malaise is a common complaint of shift workers and travelers across time zones. Along with impaired performance and other complaints, this has been attributed to the desynchronization of SCN-controlled rhythms (e.g., the sleep–wake cycle) from behavior. The discovery of a separate circadian clock raises the possibility that some of these symptoms are caused by forcing the FEO to phase shift to a new time. Unfortunately, the scientific literature regarding the role of meal timing and meal

Figure 1 Anticipatory wheel running from a rat with a lesion of the suprachiasmatic nucleus (arrhythmic when fed *ad libitum*). Food is available for 2 h day⁻¹, indicated by the vertical cross-hatched bars. Most wheel running occurs approximately 3 h before meal time. When the meal time is delayed by 8 or 10 h, anticipatory activity takes 3 or 4 days to reentrain to the phase-shifted meal. The activity persists during food deprivation (FD), but is not observed during *ad libitum* (AL) feeding.

composition in producing jet-lag symptoms in humans is extremely sparse. Only very recently has an attempt been made to assess the consequences of limiting food intake to a single meal. A carbohydrate-rich meal in the morning for 3 consecutive days led to a phase advance of 1 h of the body temperature rhythm, whereas evening meals had no effect. A similar effect has been noted in mice in that the nocturnal activity rhythm is also phase advanced if they are limited to one meal per day. In rats, the FEO is easily phase shifted by a glucose meal, but seems less responsive to a fat meal. A number of other studies indicate that there are interactions between light-entrainable and food-entrainable circadian systems; the period and phase of one has an effect on the other. Thus, there is a possibility that particular meal schedules might facilitate adjustment to temporal shifts in daily routines, but this has not yet been specifically investigated. In an interesting study, patients in a vegetative state (which reduces or eliminates the effects of activity or other external factors) received intraduodenal infusions of a liquid diet continuously, only during the day or only during the night. No consistent temperature rhythms were observed with continuous infusions, whereas day infusions resulted in a peak temperature at 8 p.m. and night infusions resulted in a peak at 4 a.m. Because these peaks

occurred at different times relative to meal onset and end, they were probably not entirely due to the thermogenic action of food but may reflect the entrainment of some physiological processes by a circadian oscillator. When humans live in temporal isolation for more than 3 weeks, approximately one-half of the subjects display internal desynchronization. The core body temperature rhythm continues to free run with a period of approximately 25 h, but the sleep-wake cycle assumes a much longer period, between 30 and 48 h. When subjects were asked to eat only two meals per day (breakfast and lunch), the interval between meals was proportional to the wake time. Before internal desynchronization, the average interval between meals was approximately 7.4 h; after internal desynchronization (when the sleep-wake cycle had assumed a period of 35.4 h), the interval increased to 10.4 h. It should be noted that subjects were entirely unaware that their sleep-wake cycle had become abnormally long. It has long been suspected that internal desynchronization is evidence for two separate circadian clocks, but alternative explanations have also been offered. In particular, none of the studies establishes the existence of a separate feeding-entrained circadian clock in humans. Nevertheless, these studies at least suggest a circadian timing component to human hunger. However, in blind humans who have difficulties adhering to a 24-h schedule, regular meals and social routines have not been very effective in forcing entrainment of the sleep-wake cycle.

In other human studies regarding the effect of light or exercise on circadian rhythms, mealtime is either not reported or small meals are given at frequent intervals so that the effects of substantial meals on physiological measures cannot be assessed. Furthermore, temperature data (and other data) are often reported as group means or in other ways that make it impossible to determine even whether temperature or serum cortisol levels in humans rise in anticipation of meals. However, the evidence is quite compelling that such rhythms persist in constant conditions, that is, that they are controlled by one or more endogenous circadian oscillators.

A nearly universal observation is that circadian rhythms adjust more readily to phase delays (e.g., westward flights) than to phase advances (e.g., eastward flights). This asymmetry is even more pronounced in rats with SCN lesions that are entrained to one meal per day. As mentioned earlier, rats can anticipate meals at intervals as long as 30 h, but have difficulty anticipating meals presented at intervals shorter than 22 h, indicating that the FEO slows down more readily than it accelerates. When meals

are shifted to a later time, anticipatory activity shifts by $2\text{--}4\text{ h day}^{-1}$ until it reaches the new phase position (see [Figure 1](#)). Conversely, after phase advances of 6 h or more, many rats display delays in anticipatory activity, again of about 3 h day^{-1} , i.e., the oscillator delays by 16–18 h over 5–6 days to catch up with the phase-advanced meal time. It is interesting that some humans also show delaying transients after rotating to an earlier shift (e.g., from the night to afternoon shift).

Conclusion

During the past decades, it has become increasingly clear that the regulation of energy balance is largely proactive rather than reactive. Circadian clocks, such as the FEO, entrain to predictable external events and ready the system for the arrival of nutrients. Phase shifts of mealtime temporarily disrupt these functions and probably account, at least partially, for the symptoms of jet lag or shift-worker malaise. The release of adrenal corticosteroids before meals could be a warning signal to the brain to replenish energy reserves. If food is consumed, serum levels decline, but if the meal is not available, serum levels might remain elevated for many hours. This, as well as other wasted physiological changes that occur in anticipation of meals, is undoubtedly not beneficial. There is no direct evidence as yet (because it has not been studied) that serious harm results from phase shifts of meals; however, it is conceivable that prolonged erratic eating habits contribute to the stress experienced by hectic modern lifestyles.

Freud in Perspective

Introduction

Sigmund Freud (1856–1939) is best known as the originator of psychoanalysis, which is at once a method of treatment for emotional disorders, a system of ideas concerning human emotional life (both healthy and disordered), and an intellectual movement. His historical significance stems from his activities in several frequently interlocking roles – theoretician,

proponent, clinician, organizer, and leader. Although practitioners of psychoanalysis have divided themselves into diverging groups adhering to different doctrines, many psychoanalysts continue to rely on Freud's theoretical conclusions and technical recommendations, and his writings are still cited in current American textbooks of psychiatry. In addition, some writers in the humanities, literary critics and historians in particular, have relied extensively on Freud's theories. Indeed, Freud's ideas, or corruptions of them, have become commonplace in Western popular culture.

Background and Personal Life

Sigmund Freud was the oldest of eight children born to a Jewish family in what was then Freiberg, in the Austro-Hungarian Empire, and is now Příbor, in the Czech Republic. His father, Jakob Freud, was a wool merchant; during hard times he moved the family to Vienna when Sigmund was 4 years old. A strong student in gymnasium and then at the University of Vienna, Freud had adolescent ambitions of becoming a leader in progressive politics but put them aside to take up the natural sciences. The geographical and social context was the Austro-Hungarian Empire, which was undergoing very rapid industrialization and modernization. Much has been written on the question of how much influence Freud's Jewish ancestry had upon his experiences, attitudes, and beliefs.

Freud's first scientific mentor was Ernst Wilhelm von Brücke, and his early laboratory studies involved comparative neuroanatomy. He earned his medical degree in 1881, but he remained a laboratory researcher for a time. He did not engage in clinical work until 1882, after he had met Martha Bernays, his future wife, and had decided that his earnings in research would never support married life. His work in neuroanatomy reached its peak in his microscopic studies of the medulla in the laboratory of Theodor Meynert. His papers on axon tracts and on his method for using gold solutions for staining them were published in both German and English in 1884, but disappointment followed when his staining method could not be replicated. Freud chose the clinical specialty of neurology – not psychiatry, which in the late nineteenth century was largely concerned with treating and studying psychotic patients in mental hospitals. As a neurologist in office practice, Freud encountered patients with symptoms that were then classified into such syndromic categories as neurasthenia and hysteria. Freud's neurological studies included important work on aphasia and paralyzes in children.

From October 1885 to February 1886, Freud studied in Paris with Jean-Martin Charcot, the premier

French neurologist of the era. Charcot was then immersed in the study of hysteria, using hypnosis to explore patients' histories and concluding that the paralyzes and seizures that he saw in his patients, and demonstrated so dramatically in his clinical presentations, had their roots in ideas. Freud's interest in these clinical problems had been stimulated by the descriptions given by his friend and senior colleague, Josef Breuer, of Breuer's treatment of the woman known in later publications as Anna O.

Freud married Martha Bernays in 1886. The couple had three sons and three daughters. In 1923, he was first given a diagnosis of oral carcinoma. This neoplasm, related to his constant cigar smoking, required several surgical procedures and produced intermittent pain over the ensuing years. Freud lived and worked in Vienna until the Nazi Anschluss in March of 1938 placed him and his family in great peril. Through the intercession of Ernest Jones and Freud's patients Princess Marie Bonaparte and William Bullitt, and diplomatic pressure by the United States, Freud was allowed to leave Austria with his wife and children in June. A condition imposed by the Germans was that Freud state that he had been treated with due respect. In response, Freud is reported to have declared "I can heartily recommend the Gestapo to anyone" – a fine example of his celebrated sense of humor. Freud spent the last year of his life in London, seeing some patients and continuing to write, despite his advanced age, until July 1939. Pain and debilitation caused by his spreading oral carcinoma then became overwhelming. On September 23, 1939, he died in what would today be called an assisted suicide.

Freud the Theoretician and Proponent

Freud generated theoretical proposals and conclusions that spanned a breathtaking range of subjects, including the technique of clinical psychoanalysis, the etiology of mental disturbances, human psychological functioning in health and disease, the pattern of development of the human personality, and the basic forces motivating human life.

Concerning the technique of clinical psychoanalysis, Freud prescribed an approach based upon anonymity, neutrality, and confidentiality and requiring from the patient free associations, meaning the vocalization of an uncensored flow of thoughts. Freud emphasized the importance of interpretations expressed by the analyst and giving meaning to dreams, feelings, and symptoms experienced by the patient. Invariably, patients encountered difficulties in reporting, or even experiencing, uncensored thoughts. Freud reported that these difficulties, termed resistances, could

themselves be understood and thus could serve to promote the exploratory process. The transference, the set of emotions experienced by the patient toward the analyst, initially seen as an obstacle to exploration, came to be seen as a crucial source of information for understanding the patient's development and reconstructing childhood relationships. The countertransference, defined as the psychoanalyst's attitudes and feelings toward the patient, subsequently received attention; Freud eventually prescribed that the analyst should undergo psychoanalysis in order to minimize its impact on the treatment.

Early in his psychoanalytic work, in 1896, Freud published his conclusion that the etiology of hysteria – the intermittent paralyses and other unexplained symptoms studied by Charcot and others – was invariably a delayed response by the patient to childhood experiences of seduction (sexual abuse or rape in today's terms) of the child by a trusted adult, typically the patient's father. Freud retracted this view within a few years and emphasized instead the significance of frustrated childhood wishes for sexual gratification by an adult.

Freud's initial psychoanalytic view of the functioning of the human mind involved what has been called a topographical model. In this conception, ideas, feelings, and wishes are processed in three different mental sectors. In the conscious sector, items that are not overly threatening could be remembered, considered, and acted upon. A preconscious sector would contain items that are not currently in awareness but that could be readily retrieved. An unconscious sector would contain extremely important memories, wishes, and feelings that would be too threatening to be recognized in consciousness. A postulated mental component known as the censor would perform the function of allowing, or preventing (through repression), items from reaching consciousness. Despite the functioning of the censor, unconscious ideation would be expressed in several interesting ways, through symptoms and symptomatic behavior, for example, or in dreams or parapraxes (slips of the tongue). In this view, an important function of psychoanalysis would be to strengthen the personality and resolve symptoms by interpreting these expressions and thereby making the unconscious conscious.

In later writings, Freud proposed a different model of mental functioning, although he never fully abandoned the topographic model. This tripartite model postulated three psychic structures. The id was described as a biologically rooted source of primitive urges. The superego, a rather rigid accumulation of prohibitions and rules imposed by parental and societal authorities, was thought to be formed in the resolution of the Oedipus complex, an emotional

situation culminating in the fourth or fifth year of life, in which the boy experiences wishes to possess his mother (emotionally and sexually) and conflicting fears of paternal retaliation and general disapproval. The ego was described as the component of the mind that can think, perceive, adapt, learn, compromise, and create; this component faces the task of reconciling demands from the other components and from the external world and enabling the person to conduct a life. In this view of mental functioning, important features of emotional life, including symptoms, choices, capabilities, and limitations, were seen as arising from conflicts between the psychic components. The task of psychoanalysis in this view would be to strengthen the ego through the development of insight into these intrapsychic conflicts.

A persistent feature of Freud's theoretical views throughout his psychoanalytic writing was the notion that no mental life would occur without energy that would have biological drives or instincts as its ultimate sources. Initially, libido or eros, a sexual drive, manifesting itself in different transformations, was seen as the sole underlying source. Later, an aggressive or destructive drive, a death instinct, was postulated in addition. This latter drive remained controversial, neither universally accepted by Freud's followers nor consistently invoked by Freud himself.

Freud had superb talents as a writer. In general, his psychoanalytic contributions were in the form of essays that were not constrained by a conventional scientific format. At times he could deploy a formidable array of rhetorical devices to convince the reader that his points were valid or even inescapable. In 1930, the city of Frankfurt honored Freud's creativity and literary accomplishments with the Goethe Prize. All of his psychoanalytic writings, with the exception of *Thomas Woodrow Wilson: A Psychological Study*, co-authored by his patient, William C. Bullitt, have been translated into English in the *Standard Edition of the Complete Psychological Works of Sigmund Freud*.

Freud the Clinician

In his earliest years as a physician and neurologist, Freud had used the standard methods of the era: a limited array of drugs, electrical currents (Faradic and Galvanic treatments), minor surgery, and hypnosis. By 1896 he was concentrating on what he called psychoanalysis. In the beginning, his analytic treatments were brief and tended to culminate in a single interpretation, but by 1896 he had begun to see at least a few patients in treatments that would last for years.

His clinical work was important for several reasons. First, since he did not directly observe the

psychoanalytic work of others, his own clinical work gave him his only opportunities to validate technical recommendations and to observe the clinical phenomena arising in psychoanalysis. Second, much of his analytic activity, especially after World War I, involved didactic psychoanalyses of trainees, and many of these trainees became productive, and useful, subordinates in the psychoanalytic movement. Third, even many of his patients who were not trainees and who never practiced psychoanalysis were prominent and wealthy people who retained a connection to Freud and his movement and proved to be helpful financially and in other ways.

Some of Freud's published discussions of individual cases, such as Schreber and Little Hans, do not refer to direct clinical psychoanalytic work conducted by Freud. His writings do contain extensive discussions of three of his own clinical cases. In the case of Dora, a young woman Freud treated in 1900, Freud reached a formulation involving an interpretation of her experience that was at variance with her own view. Freud concluded that the sexual advances from an older married man, which she had described as disturbing and unwanted, had been disturbing precisely because she had desired them, unconsciously. When Freud confronted her with this interpretation, she bolted in anger and terminated the treatment. He subsequently concluded that he had pressed this interpretation on her prematurely, but of course its validity, as well as its timing, is open to question.

Freud described the case of the Rat Man, a young army officer he treated in 1907, at length; in addition, his actual contemporaneous notes of the conduct of this analysis were discovered and published. Freud concluded that this patient suffered from an obsessional neurosis that Freud described as essentially cured by his interpretations. This case is usually seen as the most clinically successful of the ones that he described in his published works. Unfortunately, this man, later identified as Ernst Lanzer, died in 1914 at the onset of World War I, so that little longitudinal follow-up information is available.

The Wolf Man (later identified as Serge Pankejeff), a young Russian nobleman treated by Freud in 1909–1914 and later in 1919–1920, was Freud's best-studied case. Freud's published discussion focused on the Wolf Man's infantile neurosis, which Freud attempted to reconstruct. Central to Freud's formulation was his interpretation of the patient's wolf dream as symbolically referring to and describing a scene from this patient's infancy. This patient survived into the 1970s and was interviewed later in his life by two authors. Muriel Gardiner, a practicing psychoanalyst, described him as largely healed and contented. Karin Obholzer, a journalist, reported two

important findings. First, Pankejeff told her that he had received little or no clinical benefit from his psychoanalysis by Freud. Second, Pankejeff had never accepted Freud's interpretation of the wolf dream; he regarded Freud's reconstruction of a scene from his infancy as totally implausible.

Increasing quantities of information about many of Freud's psychoanalyses have gradually become available over the past half century in the form of Freud's letters, analysts' letters, memoirs and reports by analysts, and other sources. Recent revelations concerning his psychoanalytic treatments of some of his patients, such as Horace Frink, as described by Edmunds, or his daughter Anna, as described by Young-Bruehl, have sparked controversy. In a study of 43 of the cases he treated after 1907, Lynn and Vaillant found that in a majority of these cases, he deviated from the anonymity, neutrality, and confidentiality that he prescribed in his recommendations.

Freud the Organizer and Movement Leader

The development and maintenance of an organized group of psychoanalytic followers, forming a movement, always commanded Freud's attention, as shown especially in his correspondence with Ernest Jones and with Sandor Ferenczi. Freud was equally concerned with his followers' professional success, achievement of recognition, capacity to make intellectual contributions as members of his movement, and loyalty. Freud expressed his view of the optimal organization and functioning of the psychoanalytic movement in his essay *On the History of the Psycho-Analytic Movement*, first published in 1914. He envisioned a single leader with overwhelming authority. As the first leader, he wanted to find a successor who would be both capable and reliable. These considerations partly explain the pattern of his relations with a series of prominent male psychoanalysts. After apparently close collaboration, including personal friendship and mutual trust, there would be theoretical disagreement, a mutual sense of injury, competition for prominence, increasing estrangement, and repudiation. This series clearly included Carl Jung, Alfred Adler, Otto Rank, and (except for the overt repudiation), Sandor Ferenczi.

In 1912 Freud's most trusted followers, Sandor Ferenczi, Otto Rank, Karl Abraham, Ernest Jones, and Hans Sachs, formed a secret committee to oversee the movement, respond to criticisms, and assure Freud's continuing control. In his role of leader and organizer, Freud needed to reward loyalty and reliability rather than originality, creativity, or independent intellectual achievement. He generally saw

new members as converts; he referred to critics as opponents or even enemies.

Freud and Stress

Freud viewed anxiety as a signal that could refer to a number of different dangers. He was especially concerned with anxiety arising from intrapsychic threats, such as the impending emergence of repressed wishes or conflicts. In many of these situations, even the anxiety itself would be unconscious; its existence could only be inferred or deduced by the psychoanalyst. Castration anxiety, anxieties concerning unconscious homosexual wishes, and anxieties concerning unconscious incestuous wishes were frequently invoked in the formulation and interpretation of patients' experiences and symptoms. Freud's work did not direct attention to the biological aspects of states of anxiety, nor to the role played by overwhelming external stressors. Even in his brief discussions of war neuroses, Freud emphasized intrapsychic conflict as the essential element that either made these neuroses possible or promoted them. Freud's influence was reflected in the official diagnostic terminology of American psychiatry codified in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-I) (1952) and retained in the DSM-II (1968). These listings explicitly described anxiety as an intrapsychic signal, included anxiety disorders as neuroses, and excluded any anxiety disorder specifically related to an external stressor (such as the current posttraumatic stress disorder).

Freud in Perspective

Sigmund Freud must be seen as one of the most influential intellectuals of the twentieth century. There is no indication that the influence of his system of ideas in such fields as literary criticism and historical analysis, or in the general popular culture, will recede.

Within the medical profession, Freud's ideas gained their greatest influence in American psychiatry in the middle of the twentieth century. As late as the 1970s, American psychiatry was divided into schools of thought, each of which had its own journals and took its own approach to the definition of problems to be studied, the terminology to be used, the clinical methods to be advocated, and the basic etiological assumptions to be adopted. An adherent of a particular school often felt no obligation to read or consider contributions from other schools. In this context, the extent of the influence that Freud's system of ideas

had upon psychiatrists was very uneven. At one extreme, for some psychiatrists in some departments, Freud's conclusions were seen as scientifically established discoveries that served as the basis for any treatment or any academic discussion. In other departments, Freud's conclusions were either explicitly rejected or, more frequently, ignored. In recent years, American psychiatry has taken important steps toward a systematically scientific approach to clinical issues. In general, training programs no longer explicitly adopt locally accepted assumptions, and advocates of any treatment approach are expected to produce data supporting their claims.

In this current environment, Freud's conclusions will retain influence to the extent that they can be validated with reproducible results. (Advocates of psychoanalysis cannot, in this context, adequately deal with skeptics by simply maintaining that nobody has conclusively demonstrated that the method does not work.) Freud's own psychoanalytic publications have shortcomings that limit the extent to which they can be used as validation: a lack of raw observational data, an inadequate description of Freud's actual methods, and a commingling of postulates, hypotheses, observations, conclusions, and speculations without adequate designation. The psychoanalytic situation contains unavoidable difficulties for any clinical researcher in the collection and verification of data, in the generation of adequate numbers of cases, and in the standardization of technique between analysts. Efforts by latter-day psychoanalysts to validate conclusions through systematic outcome research have not produced any conclusive results, and it is unclear how, and by whom, such studies would be carried out in the future.

Introduction to the Role of GABA as a Neurotransmitter
Neuronal Receptors for GABA
GABAergic Neurons and Their Role in Neuronal Activity

Glossary

<i>Amino acid</i>	A small organic molecule consisting of a backbone to which is attached an amino group ($-\text{NH}_2$) and an acidic group ($-\text{COOH}$). Twenty naturally occurring amino acids are incorporated into proteins under direct genetic control.
<i>Benzo-diazepine</i>	The generic name for a class of chemical substances that are in wide clinical use for their anxiolytic, sedative, and muscle-relaxant properties. These actions are produced by enhancing inhibitory transmission at synapses that use GABA as a transmitter.
<i>Subunit</i>	The receptors for many neurotransmitters are composed of a number of (usually five) distinct proteins encoded by separate genes. When the receptor is assembled from identical subunits encoded by a single gene, the assembly is termed homomeric; when subunits encoded by different genes are incorporated, the assembly is termed heteromeric.
<i>Synapse</i>	The very small contact area between two nerve cells where chemical transmission occurs. The chemical messenger (the neurotransmitter) is stored in vesicles in the presynaptic terminal. Nervous activity causes these vesicles to release the neurotransmitter into the synaptic cleft, following which it activates specific

receptors on the postsynaptic membrane. These transduce the chemical message into an electrical signal, which can be either excitatory or inhibitory.

Gamma aminobutyric acid (GABA) is the principal inhibitory transmitter in the central nervous system (CNS). GABA acts on three distinct receptor complexes: GABA_A , GABA_B , and GABA_C receptors. GABA_A receptors are heteromeric structures assembled from 5 subunits selected from up to 16 different glycoprotein subunits. This heterogeneity confers discrete pharmacological and physiological properties on the assembled complex. The five subunits surround a central ion-selective channel, which conducts chloride ions into the neuron when GABA binds to the receptor. This inhibits the neuron by causing an increase in membrane potential and conductance. The GABA_A receptor complex also contains a number of distinct modulatory sites that are the target for many neuroactive and therapeutic drugs, including benzodiazepines, barbiturates, steroids, alcohol, and a variety of general anesthetics. The activation of these modulatory sites generally enhances neuronal inhibition at GABA_A synapses, which probably accounts for the anxiolytic, sedative, hypnotic, and anesthetic properties of these substances.

GABA_B receptors are formed by a single protein molecule that is coupled with intracellular enzymes and effector systems. These can activate K^+ -selective channels, which inhibits the neuron, or depress the activity of Ca^{2+} -selective channels, which decreases transmitter release from presynaptic terminals. GABA_C receptors have many structural and functional similarities to GABA_A receptors, but they exhibit sufficient pharmacological and mechanistic differences to merit classification as a separate receptor.

In view of its ubiquitous role in the integration of neuronal activity, it is hardly surprising that dysfunction of GABAergic transmission has been implicated in a wide variety of neurological and psychiatric

disorders, including epilepsy, anxiety states, alcoholism, nociception, Huntington's chorea, and other movement disorders.

Introduction to the Role of GABA as a Neurotransmitter

GABA was already shown to be present in the CNS in 1950. Using the technique of microiontophoresis to apply pharmacologically active substances to single

neurons in the CNS, it was subsequently shown that GABA caused a powerful inhibition of virtually every neuron to which it was applied. This, along with its simple structure and ubiquitous occurrence, meant that there was initially great skepticism as to whether GABA could fulfill the criteria required for a central inhibitory transmitter (see [Box 1](#)). These doubts were allayed by the use of two naturally occurring substances that potently and selectively block the actions of exogenously applied GABA, as well as synaptic

Box 1

Classification of GABA Receptors

A single neurotransmitter usually activates a number of distinct postsynaptic receptors. These are distinguished and identified on the basis of their responses to the actions of agonists and antagonists. Agonists are molecules that bear a chemical resemblance to the natural transmitter and, on binding to the receptors, are able to operate the effector system and thereby mimic the response to the transmitter itself. As the name implies, antagonists prevent the agonist from evoking a response. There are two main classes of antagonist: competitive and noncompetitive. Competitive antagonists bind to the receptor site, but are unable to operate the effector system. However, they impede access of the agonist (including the natural transmitter) to the receptor site and thereby block the response. Bicuculline is an example of a competitive antagonist at GABA_A receptors, and CGP 55845A competitively antagonizes responses at GABA_B receptors. Noncompetitive antagonists do not interact with the receptor itself but block the action of the effector mechanism. Picrotoxin, for example, binds

within the ionophore, which is gated by the GABA_A receptor, and thereby inhibits the response to GABA.

On the basis of such pharmacological studies, three main families of postsynaptic receptors for GABA have been identified. These have simply been named alphabetically in the chronological order of their discovery: GABA_A, GABA_B, and GABA_C receptors. The table shows the structural, pharmacological, and mechanistic features of these three receptors. GABA_A and GABA_C receptors are both pentameric structures surrounding a Cl[−]-selective ionophore. GABA_C receptors have been accorded their own classification based primarily on their lack of sensitivity to bicuculline and lack of modulatory sites. GABA_B receptors are coupled to intracellular enzymes and other mechanisms that mediate the response. Although GABA_A and GABA_B receptors obviously share the same natural transmitter, they otherwise have very little in common, either with respect to their molecular structure, pharmacology, or mechanism of action.

Specific properties of GABA receptors

	GABA _A	GABA _B	GABA _C
Receptor mechanism	Cl [−] -selective ionophore	G-protein-coupled metabotropic receptor	Cl [−] -selective ionophore
Receptor composition	Pentamer constructed from α_{1-6} , β_{1-4} , γ_{1-4} , δ_1 , and ϵ_1	Dimer constructed from GABA _B R1 + GABA _B R2	Pentamer constructed from ρ_{1-2}
Single channel conductance	≈30 pS	—	≈8 pS
Mean channel open time	≈25 ms	—	≈150 ms
Receptor desensitization	Yes	No	No
Potency of GABA (EC ₅₀) ^a	≈10 μ M	≈10 μ M	≈1 μ M
Selective agonist	THIP, ^b P4S ^c	Baclofen	CACA ^d
Selective antagonist	Bicuculline	Saclofen, CGP 55845A	3-APA ^e

^aMedian effective concentration.

^b4,5,6,7-Tetrahydroisoxazole[4,5-c]pyridin-3-ol.

^cPiperidine-4-sulfonic acid.

^dThere are no potent selective agonists for GABA_C receptors, but cis-4-amino crotonic acid is a partial agonist.

^e3-Aminopropylphosphonic acid.

potentials evoked by the stimulation of inhibitory nerves. These substances are the alkaloids bicuculline and picrotoxin, which have played a pivotal role in past and present research on GABAergic inhibition. The ability of both alkaloids to cause sustained seizures and convulsions was known long before their actions on GABA receptors were resolved. However, this provided the first clue as to how manipulation of the GABAergic system could alter the state of excitability in the nervous system.

In 1980, a bicuculline-insensitive action of GABA was discovered that could be mimicked by the antispastic agent baclofen. A pharmacologically distinct receptor for GABA had been identified, and it was decided to name receptors alphabetically in chronological order of their discovery: bicuculline-sensitive receptors were termed GABA_A, and bicuculline-insensitive receptors were termed GABA_B.

Early studies of inhibition mediated by GABA_A receptors at various sites in the CNS had disclosed discrete differences in the responses, which implied the existence of different isoforms of the receptor. Following its cloning in the late 1980s, it became apparent that the GABA_A receptor is assembled from five subunits and that the identity of these determines the properties of the assembled complex. These studies also led to the identification of pharmacologically distinct GABA_C receptors. The classification of the GABA receptors is given in [Box 1](#).

Neuronal Receptors for GABA

GABA_A Receptors

The GABA_A receptor is a heterooligomeric complex that is probably assembled from five subunits. These are grouped around a central ion-conducting channel (ionophore), which is opened when two molecules of GABA (or another agonist) bind to the receptor. The subunits are encoded by at least 16 genes, which are grouped into five families: α_{1-6} , β_{1-4} , γ_{1-4} , δ_1 , and ϵ_1 . The degree of sequence homology of amino acids within each family is around 70%, whereas it is less than 30% between the families. Furthermore, the mature mRNAs for α_6 , β_2 , β_4 , and γ_2 can be alternatively spliced to include or omit amino acid sequences, yielding long (L) or short (S) versions of these subunits, respectively. The subunits, which are composed of around 500 amino acids (molecular mass ranging from 48 to 64 kDa), have a similar topographical structure with the following features:

1. A large extracellular N-terminal domain containing the binding site (receptor) for GABA and a variety of modulatory ligands. This region also contains two to four glycosylation sites, which

could be important for the intracellular sorting and assembly of proteins.

2. Four hydrophobic transmembrane domains (TM1–4), which are linked by polypeptide chains. TM2 contains clusters of basic amino acids, which are believed to line the channel wall and determine its selectivity to anions.
3. A large intracellular loop connecting TM3 and TM4 that in some subunits contains sites that can be phosphorylated. Whether phosphorylation increases or decreases receptor function depends on the enzyme involved.

If there were no restrictions on how the subunits could assemble, an immense number of isoforms would exist. However, there are certain constraints on which combinations can form functional complexes. Thus, the presence of an α subunit is essential for producing a functional channel, and the GABA_A receptor itself is probably located at the interface between two dissimilar subunits. The overall stoichiometry of the pentamer is likely to be two α , two β , and one γ subunits, which are arranged alternately ([Figure 1](#)). The α subunits need not be identical and the γ subunit can be replaced by a δ or an ϵ subunit. *In situ* hybridization and immunoprecipitation studies have shown that approximately 20 isoforms account for the vast majority of GABA_A receptors, which are expressed in the CNS in a structure and cell-specific manner ([Table 1](#)). The most abundant combination is $\alpha_1 \beta_2 \gamma_2$, which accounts for almost half the receptors and is expressed in most brain regions. Different subunit combinations are often expressed within the same neuron.

This repertoire of 20 isoforms is sufficient to confer substantial functional and pharmacological diversity on the GABA_A receptors. Examples of this diversity include the sensitivity to GABA, the kinetics of operation of the ionophore, and the actions of modulators. An interesting example of how these properties are exploited concerns the expression of GABA_A receptors during development of the CNS.

GABA_A receptors are expressed in the membrane some time before specialized synaptic contacts develop. The α subunit is selected from α_2 , α_3 , or α_5 , which form receptors having a relatively high affinity for GABA and respond to ambient levels of GABA in the extracellular fluid. The intracellular Cl[−] concentration is relatively high early in development: E_{Cl^-} is positive to the resting membrane potential and the activation of the GABA_A receptors evokes an excitatory response (see [Box 2](#)). This depolarization activates voltage-dependent Ca²⁺ channels and the influx of Ca²⁺ activates a host of intracellular processes, which contribute to the neurotrophic response.

Figure 1 The molecular structure of GABA receptors. a, GABA_A receptor complex; b, GABA_B receptor. (a) The GABA_A receptor complex is assembled from five individual subunits (with an overall stoichiometry of 2 α , 2 β , and 1 γ) that surround a central chloride-selective channel (ionophore). The insert shows an individual subunit, which is composed of approximately 500 amino acids and has four transmembrane domains (TM1–4). Two GABA binding sites (receptors) are located between the α and β subunits. The GABA_A receptor also contains a number of modulatory sites. The benzodiazepine receptor is located at the interface between α and γ subunits, whereas the receptors for steroids and barbiturates show little subunit specificity (indicated by the multiple arrowheads). Anesthetics, ethanol, and the convulsant picrotoxin exert their actions at sites associated with the channel. The areas marked by an encircled P on the inside of the channel denote sites that can be phosphorylated and that modify channel function. (b) The GABA_B receptor has seven transmembrane domains (I–VII) with a large extracellular N-terminal region that forms the receptor for GABA. The complex is coupled to a G-protein complex on the inside of the membrane, which mediates the cellular effects following receptor activation. The lower diagram shows the functional GABA_B receptor. This is a dimer formed by two receptors, GABA_BR1 and GABA_BR2, which associate at the C-terminal region. Adapted from (a) McKernan and Whiting (1996); (b) Kaupmann et al. (1998); Kuner et al. (1990).

Table 1 Distribution of the major GABAA receptor subtypes in the rat brain^a

GABA _A receptor subtype	Relative abundance (%)	Location and putative function
$\alpha_1 \beta_2 \gamma_2$	43	Most brain areas Interneurons in hippocampus and cortex Cerebral Purkinje cells
$\alpha_2 \beta_{2/3} \gamma_2$	18	Spinal cord motoneurons Hippocampal pyramidal cells
$\alpha_3 \beta_n \gamma_2/\gamma_3$	17	Cholinergic and monoaminergic neurons
$\alpha_2 \beta_n \gamma_1$	8	Bergmann glia Nuclei of the limbic system
$\alpha_5 \beta_3 \gamma_2/\gamma_3$	4	Predominantly hippocampal pyramidal cells
$\alpha_6 \beta \gamma_2$	2	Cerebellar granule cells
$\alpha_6 \beta \delta$	2	Cerebellar granule cells
$\alpha_4 \beta \delta$	3	Thalamus and hippocampus dentate gyrus
Other minor subtypes	3	Present throughout the brain

^aAdapted from McKernan and Whiting (1996).

Synaptogenesis starts about 2 weeks after birth. The receptors cluster at the postsynaptic density and are exposed to a high concentration of GABA released from the presynaptic vesicles (see [Box 3](#)). These receptors predominantly contain the α_1 subunit, which has a relatively low affinity for GABA and is less susceptible to activation by extrasynaptic GABA. Meanwhile, an outwardly directed Cl^- transporter reduces the intracellular Cl^- concentration, and Cl^- becomes negative with respect to the resting membrane potential. The activation of the synaptic GABA_A receptors then produces the familiar inhibitory response.

Another example of the exploitation of receptor diversity is that α_1 subunits are expressed throughout the somatodendritic axis of hippocampal CA1 pyramidal neurons, whereas α_2 subunits are expressed on the initial segment of the axon ([Table 1](#)), where the output signal is generated (see [Box 2](#)).

Modulatory sites associated with GABA_A receptors

The receptors for a number of therapeutically important drugs are associated with the GABA_A receptor complex. Separate and distinct receptors have been identified for benzodiazepines, barbiturates, and steroids, whereas alcohol and some general anesthetics also act through the GABA_A system ([Figure 1](#)). The binding of ligands to these receptors does not generally operate the GABA_A ionophore directly. Rather, these act as modulatory sites that are allosterically coupled to GABA_A receptors. The occupation of a modulatory receptor increases the affinity of the GABA_A receptor and thereby increases the probability that the ionophore will open in response to GABA. Synaptic inhibition is prolonged, which depresses activity in neuronal networks. The therapeutic and behavioral effects of actions at modulatory sites are (in ascending order): anxiolytic → sedative → hypnotic → anesthetic.

Benzodiazepines The action of benzodiazepines shows subunit specificity. The minimum requirement for benzodiazepine sensitivity is an α subunit selected from α_1 , α_2 , α_3 , or α_5 , together with either a γ_2 or γ_3 subunit. The benzodiazepine receptor itself is probably located at the interface between the α and γ subunits. Benzodiazepines have no actions at receptors containing α_4 , α_6 , or γ_1 subunits, whereas the identity of the β subunit seems to have little influence on the effect of benzodiazepines.

The benzodiazepine receptor possesses the unique feature that the identity of the ligand determines whether it will interact positively or negatively with the GABA_A receptor. Agonists at the benzodiazepine receptor (such as diazepam and flunitrazepam) increase the likelihood that the ionophore will open in response to GABA and have therapeutic profiles as anxiolytic, anticonvulsant, sedative, and hypnotic. On the other hand, inverse agonists such as the β -carboline, β -CCM, and DMCM decrease the probability of channel opening, and their behavioral profile is correspondingly proconflict and proconvulsant. Benzodiazepine receptor antagonists block the actions of both agonists and inverse agonists.

In accordance with the intense efforts devoted to this therapeutically important locus, at least seven chemical classes of substances have been identified that interact with the benzodiazepine receptor. Investigations with representatives of these have shown further discrete subunit-dependent actions and have helped identify two main subtypes of benzodiazepine receptor. BZ₁ receptors have a high affinity for diazepam and β -CCM. They are characterized by containing an α_1 subunit and are widely expressed in the CNS (particularly the cerebellum). BZ₂ receptors have a high affinity for diazepam but a low affinity for β -CCM. BZ₂ receptors contain α_2 , α_3 , or α_5 subunits and are mainly expressed in a complementary pattern

Box 2**Why GABA Is an Inhibitory Transmitter**

In order to understand why and how GABA acts as an inhibitory transmitter, it is necessary to consider the electrochemical basis of neuronal activity, which is illustrated in the accompanying diagrams.

(a) There is a potential difference across the membrane of the resting neuron, with the inside being approximately -70 mV with respect to the outside. This potential arises because of the asymmetrical distribution of the major monovalent ions (Na^+ , K^+ , and Cl^-) across the membrane. The diagram shows representative ionophores for these ions, along with their relative concentrations on both sides of the membrane. The resting membrane is relatively permeable to K^+ and Cl^- , but it is impermeable to Na^+ (indicated by the relative sizes of the channels through the ionophores). Each ionic species is under the influence of two gradients: a chemical gradient (**c**) favoring movement from high to low concentration and an electrical gradient (**e**) favoring movement toward the opposite polarity. The net driving force on a particular ion is given

by the sum (e.g., for Na^+) or difference (e.g., for K^+ and Cl^-) of these two gradients. In order to compare these gradients directly, the Nernst equation is used to convert the concentration gradient to an equivalent electrical gradient, the values of which are given on the arrows representing the chemical gradient and on horizontal lines in part (b). When the potential gradient exactly counterbalances the concentration gradient, equilibrium pertains and no net ionic movement occurs.

(b) A diagram of potential levels showing resting membrane potential (RMP), the equilibrium potentials for the ions (E_{Na^+} , E_{K^+} , E_{Cl^-}), and the threshold for action potential generation (E_{Thresh}). Zero potential is also shown for reference. A selective increase in membrane permeability to one of the ions causes it to move down its electrochemical gradient (ecg), and the membrane potential moves toward the equilibrium potential for that particular ion. Such a change in permeability can arise because the nerve cell membrane contains a multitude of

Box 2
Continued

different ion-selective channels that can be activated (gated) by changes in the transmembrane potential or by the binding of ligands and transmitters as to specific receptors (e.g., GABA). A selective increase in Na permeability (i) results in a depolarization and, if E_{Thresh} is reached, evokes a regenerative action potential (AP, stippled line). The AP is a positive-going potential of approximately 100 mV lasting for 1–3 ms and is the output signal of the neuron. Factors that move the membrane potential toward E_{Thresh} increase the likelihood of neuronal firing and are therefore termed excitatory. Conversely, increasing the membrane potential (hyperpolarization) makes it less likely that the neuron will fire an AP, and these influences are therefore inhibitory. GABA is an inhibitory transmitter because it acts on GABA_A and GABA_B receptors to cause a selective increase in permeability to Cl^- ions (ii) and K^+ ions (iii). Because both E_{Cl^-} and E_{K^+} are more negative than the resting membrane potential, action at both receptors causes a hyperpolarization, which inhibits the neuron. This hyperpolarization is, however, not the only reason why the neuron is inhibited.

(c) It is also necessary to consider the spatial interactions between excitatory and inhibitory synapses. A typical nerve cell consists of a cell body (soma)

from which a more or less extensive dendritic tree arises. This acts as the receiving and integrating area for excitatory and inhibitory synaptic contacts. The axon also arises from the soma and conducts the APs to the terminals where it causes transmitter release. The initial segment of the axon (or axon hillock) has the highest density of voltage-gated Na^+ channels and therefore the lowest threshold for AP generation. As to whether this threshold is reached depends on the ongoing integration of synaptic activity on the somatic and dendritic membranes. (1) A representative excitatory synapse is selectively activated. These synapses use glutamate as a transmitter, which gates ionophores that are selectively permeable to Na^+ . Positive current flows into the postsynaptic membrane at the synapse. Because the bilipid membrane has a high resistance, this current can flow relatively long distances within the neuron before exiting through the membrane and returning to the active synapse to complete the current loop. This spread of current allows the possibility of both spatial and temporal summation with activity at other synapses. For example, if a sufficient number of excitatory synapses are activated, the initial segment is depolarized to firing level and an AP arises. (2) Inhibitory GABA_A synapses are

(c)

Box 2
Continued

usually located close to the soma, where they can exert a correspondingly greater influence on the initial segment. The selective activation of the inhibitory synapses causes Cl^- ions to move through the ionophore (which is equivalent to an outward movement of positive current, as shown by the direction of the arrowhead), which results in an IPSP. (3) When excitatory and inhibitory synapses are

activated simultaneously, the GABA_A ionophores provide a low-resistance pathway through which the excitatory current will pass. This means that much less depolarizing current reaches the initial segment and the output of the neuron is inhibited. Thus, GABA_A synapses inhibit the neuron both by causing a hyperpolarization and by shunting excitatory synaptic activity.

to BZ_1 receptors (i.e., where the concentration of α_1 is low). Note that the aforementioned changes in receptor composition during development actually represented a shift from BZ_2 to BZ_1 receptors.

Barbiturates and steroids The GABA_A receptor is also modulated by barbiturates and certain metabolites of gonadal and adrenal hormones (such as progesterone and deoxycorticosterone, respectively). When synthesized in the brain, these metabolites are termed neurosteroids (to distinguish them from neuroactive steroids, which may be synthesized elsewhere) and are therefore an endogenous ligand for a modulatory site associated with the GABA_A receptor. Steroids were originally thought to interact with the barbiturate receptor until the separate identity of the two receptors was established.

The actions of barbiturates and steroids have much more in common with one another than they do with benzodiazepines. Barbiturates and steroids potentiate responses to GABA by prolonging the duration of channel open time, which contrasts to the increase in frequency of channel openings produced by benzodiazepine agonists. Furthermore, at concentrations greater than are required for the modulatory effect on GABA_A receptors, both barbiturates and steroids can gate the ionophore directly by an action that does not involve the GABA_A receptor itself. Such direct gating is never seen with benzodiazepines. Antagonists of the steroid receptor have been characterized (e.g., dehydroepiandrosterone), but so far no antagonists of the barbiturate receptor have been identified.

The actions of barbiturates and steroids do not show absolute subunit dependency, although their effects may be influenced more subtly by the actual composition of the receptor. The therapeutic and behavioral actions of barbiturates and steroids are generally much more pronounced than benzodiazepines. The former tend to cause heavy sedation and anesthesia, whereas benzodiazepines generally have milder effects. The lack of subunit specificity means barbiturates and steroids are likely to enhance GABA_A ergic

actions more globally and indiscriminately. For example, the GABA_A receptors expressed in the thalamus do not contain γ subunits (Table 1) and are not, therefore, responsive to benzodiazepines. The responses are, however, enhanced by barbiturates and steroids.

Other agents that modulate activity of the GABA_A receptor In addition to the barbiturate anesthetics, a wide range of other anesthetics appear to potentiate responses mediated by GABA_A receptors. These include the inhalation anesthetics halothane, isoflurane, and diethylether and the intravenous anesthetics propofol and etomidate. Augmentation of GABA_A ergic transmission is likely to make a marked contribution to the anesthetic action of these substances.

GABA_A ergic transmission is also modulated by ethanol. Interestingly, the effect of ethanol seems to be mediated by phosphorylation of the γ_{2L} subunit.

Side effects of agents that act at the GABA_A receptor Familiar problems are associated with long-term therapeutic treatments with many agents that act at the GABA_A modulatory sites. Prolonged use of benzodiazepines, barbiturates, and ethanol all cause tolerance, which is followed by dependence and addiction. There are also manifestly unpleasant symptoms on withdrawal of treatment. The increasing knowledge of the structure and function of the GABA_A receptor subtypes has intensified efforts to develop drugs that act at specific subunits (or combinations thereof). These would have a narrower clinical profile with fewer side effects and could be used for conditions such as anxiety, epilepsy, and insomnia.

GABA_B Receptors

The GABA_B receptor is formed by a single protein containing seven hydrophobic transmembrane domains and a large N-terminal extracellular domain that forms the receptor for GABA (Figure 1). This structure is characteristic of metabotropic receptors, which are not coupled directly to an ionophore but exert their

Box 3Synaptic Transmission at a GABA_A Synapse

GABA fulfills the following criteria required for a neurotransmitter: it is present in the nerve terminal, it is released upon nerve stimulation, it activates specific receptors on the postsynaptic membrane, a specific uptake mechanism is available to remove it from the extracellular fluid, and its direct application to neurons mimics the effect of nerve stimulation. These aspects are illustrated in the accompanying diagram, which depicts the sequential steps (a–j) in synaptic transmission at a GABA_Aergic synapse.

The GABA_A synapse contains pre- and postsynaptic specializations at the area called the active zone. Four active zones are illustrated, each represented by a single presynaptic vesicle opposed by a single receptor complex in the postsynaptic membrane. The synaptic cleft is approximately 100 nm wide. (a.) Vesicles filled with GABA are docked at the presynaptic specialization in close proximity to a

voltage-sensitive Ca²⁺-selective channel. (b.) On arrival of an action potential at the nerve terminal, the Ca²⁺-selective channel opens transiently. (c.) Ca²⁺ ions pass into the terminal and bind to four Ca²⁺ sensors associated with the vesicle. This causes exocytosis of the vesicle and GABA is expelled into the synaptic cleft, where it quickly reaches a peak concentration of approximately 500 μM. The empty vesicle leaves the membrane and is recycled. (d.) The binding of two molecules of GABA to each receptor complex causes the subunits to tilt slightly. This opens the ionophores and allows Cl[−] ions to flow across the postsynaptic membrane. (e.) Recordings from single-receptor complexes using the patch-clamp technique have shown that the ionophore flickers between open and shut states in the presence of GABA. Current flowing through the whole ensemble of 20–30 ionophores clustered together at the active zone creates a smooth, but transient, potential

Box 3

Continued

change across the postsynaptic membrane. This is termed the inhibitory postsynaptic potential (IPSP), and lasts approximately 50 ms. The reasons why the IPSP depresses neuronal activity are given in [Box 2](#). Although 90% of the GABA released from the vesicle has diffused away from the active zone within 0.5 ms, some molecules still remain bound to the receptor complexes. However, these ionophores close of their own accord. This process is known as desensitization, and it is thought to protect the GABA_A receptors from overactivation. (f.) Synaptically released GABA is ultimately removed from the extracellular fluid by uptake transporters (GAT) located on both neurons and the supportive glia cells. (g.) The enzyme GABA-transaminase (GABA-T) catalyzes the conversion of GABA and α -ketoglutarate (KG; derived from glucose metabolism) to succinic semialdehyde (SSA) and glutamate (Glu). Glutamate, which cannot cross the extracellular space because it is neuroactive, is then

converted to glutamine (Gln) by the enzyme glutamate synthase. Glutamine diffuses across the membranes and into the presynaptic terminal, where it is reconverted to glutamate by glutaminase, which in turn is converted to GABA by glutamic acid decarboxylase (GAD). (h.) Specific transporters fill the recycling vesicles with GABA, where it is stored at a concentration of approximately 100 mM. These dock with the presynaptic membrane at the active zone, thereby completing the cycle. (i.) GABA_B autoreceptors located on the presynaptic terminal are activated by GABA present in the extracellular space. These are negatively coupled to the Ca²⁺ channels by G-proteins. The depression of Ca²⁺ entry through these channels decreases vesicle release in response to subsequent activation. (j.) Postsynaptic GABA_B receptors are positively coupled by G-proteins to K⁺-selective channels. This mediates a slow IPSP, thereby inhibiting the postsynaptic neuron.

actions via second messengers that alter the activity of intracellular enzymes and other mechanisms.

Two splice variants of the GABA_B receptor, GABA_BR1a and GABA_BR1b, were originally cloned and tested for their ability to mimic the effects of native GABA_B receptors. Although they showed a similar sensitivity to antagonists, their affinity for GABA was approximately 100 times less than the native receptors. Moreover, when expressed in mammalian cells, they showed poor translocation to the membrane and coupled only weakly to the effector mechanisms. The reasons for these anomalies have recently been resolved with the cloning and characterization of a second GABA_B receptor, GABA_BR2. This has 35% sequence homology with the GABA_BR1 receptor and has a similar structure. The two receptors associate together at the C-terminus. This is expressed in the cell membrane as a functional dimer, where it displays the characteristics of the native GABA_B receptor. The binding of GABA to this dimer causes the activation of GTP-binding proteins (G-proteins) on the inside of the membrane. Depending on the identity of the G-protein, this stimulates or inhibits effector enzymes (e.g., adenylyl cyclase and phospholipase C) and proteins (e.g., ionophores), which mediate the cellular response. The binding of a single molecule of GABA to the GABA_B receptor activates many molecules of G-protein, thereby amplifying the response greatly. However, due to the number of intermediate steps involved, G-protein-mediated transduction is characterized by a relatively

long latency (around 40 ms), followed by a time course of action lasting a second or more.

GABA_B receptors mediate two location-specific effects. On postsynaptic dendritic membranes, the G-proteins are positively coupled to a K⁺ selective ionophore. Because E_{K^+} is negative to the resting membrane potential (see [Box 2](#)), the activation of these channels gives rise to a relatively large inhibitory postsynaptic potential (IPSP), which lasts for 1–2 s. GABA_B receptors are also located on presynaptic terminals where they are negatively coupled to the voltage-dependent Ca²⁺ channels. The reduction of Ca²⁺ flux through these channels reduces the probability that a vesicle will be released in response to an action potential (AP) and thereby decreases synaptic transmission. These GABA_B receptors are located on the presynaptic terminals of a variety of neurons that use a range of transmitters. In the special case in which they are located on the terminals of GABAergic neurons themselves, they are termed autoreceptors. During repetitive activity, these autoreceptors serve to decrease the synaptic release of GABA, which will promote the expression of postsynaptic excitatory responses from other sources.

Although pre- and postsynaptic GABA_B receptors apparently show differences in their sensitivity to agonists and antagonists, it is presently unresolved as to whether these represent pharmacologically distinct receptors. Furthermore, it is not certain to what extent GABA_B receptors are located within the postsynaptic density (see [Box 1](#)). They are certainly

expressed at extrasynaptic sites, where they respond to ambient levels of GABA in the extracellular fluid (which partly arises as spillover from nearby GABA_A synapses). This notion that GABA_B receptors play more of a neuromodulatory role rather than a direct-transmitter role is supported by the fact that relatively strong stimulation of GABAergic neurons is required to activate pre- and postsynaptic GABA_B receptors.

GABA_B receptors show high concentrations in certain regions of the CNS, including the cerebellum, thalamus, and spinal cord. Although this pattern is distinct from that of GABA_A receptors, there are many regions where the two receptors overlap. It is likely that the majority of single neurons express both GABA_A and GABA_B receptors.

Effects mediated by GABA_B receptors have been implicated in the neuronal processes associated with memory (long-term potentiation), slow-wave sleep, muscle relaxation, and antinociception. The GABA_B agonist, baclofen, has long been in clinical use as an antispastic agent and also shows promise in the treatment of chronic pain and withdrawal symptoms from cocaine. GABA_B receptor antagonists do not presently have clinical applications, but have been shown to be effective in animal models of absence epilepsy and cognitive impairment.

GABA_C Receptors

GABA_C receptors are formed from homo- or heteromeric assemblies of ρ_1 or ρ_2 subunits and are structurally and functionally similar to GABA_A receptors. Although ρ subunits are probably the ancestral form of the GABA_A subunits, they do not apparently assemble together with other subgroups. GABA_C receptors are characterized by their lack of sensitivity to bicuculline and high sensitivity to GABA (Box 3). The GABA_C-operated ionophores have a substantially lower conductance than the GABA_A ionophores (probably because its diameter is slightly smaller), and they do not desensitize in the maintained presence of GABA. Finally, GABA_C receptors lack the modulatory sites associated with the GABA_A receptor. Functional GABA_C receptors have so far been demonstrated only in the retina. However, ρ subunits occur at many other sites in the CNS (e.g., the cerebellum), and mRNA for ρ_2 is present throughout the brain.

GABAergic Neurons and Their Role in Neuronal Activity

Because the only known function of GABA is to act as an inhibitory neurotransmitter, GABAergic neurons may be identified by histochemical demonstration

of the synthesizing enzyme, glutamic acid decarboxylase (GAD). The majority of GABAergic neurons are interspersed between the principal neurons of a given anatomical structure; then they are termed interneurons. However, they can also have long axons that project to other regions in the CNS. Although sharing the same transmitter, GABAergic neurons otherwise exhibit a wide range of morphological, histochemical, and functional characteristics. For example, at least a dozen distinct types of GABAergic neurons can be identified in the cerebral cortex.

Some of these have very narrow axonal fields confined to a cortical column, whereas others have extremely extensive axonal arborizations that can extend over large distances. GABAergic neurons themselves are under the control of other synaptic influences: they are excited by glutamatergic synaptic inputs and inhibited by other GABAergic neurons. The nature and degree of synaptic inhibition they produce on the neurons with which they form synaptic contacts depends on

1. Their intrinsic membrane properties and firing patterns. Many GABAergic neurons are able to fire APs at relatively high frequencies with little accommodation. This maximizes GABA release at the terminals (which in turn may be under the feedback control exerted by autoreceptors).
2. The number and location of the synaptic contacts on the postsynaptic membrane. Such contacts do not occur randomly but are placed in a strict topographical order on the postsynaptic membrane.
3. The identity of the postsynaptic receptors (e.g., GABA_A or GABA_B receptors and their possible subtypes).

By controlling the excitability of the postsynaptic neuron, GABAergic neurons participate in the regulation of network activity. Expressed in its simplest form, GABAergic inhibition curtails the activity of principal neurons in response to an excitatory synaptic input (feed-forward inhibition) and after an output signal has been generated (feedback inhibition) (Figure 2). These inhibitory influences act as a brake on the principal neuron, which could otherwise enter an unstable oscillatory state in which relatively modest excitation can result in an explosive response. Indeed, pharmacological blockade of GABAergic inhibition is often used in experimental situations to evoke activity that is reminiscent of epileptic discharges. It is becoming increasingly evident that GABAergic inhibition cannot be regarded simply as a counterweight to intrinsic and synaptic excitatory processes. GABAergic synapses participate in the spatiotemporal integration of activity in neuronal networks and thereby play a major role in the processing of information. GABAergic neurons are

Figure 2 The role of GABA receptors in determining network excitability. The diagram shows how GABAergic inhibition controls the activity of principal neurons (PN). Only single synapses of each type are shown for clarity. Stimulation of the afferent input pathway (bottom left) evokes an action potential, which spreads in the nerve fiber (arrows). This ultimately results in a compound synaptic response in the PN (shown on the right), the components of which arise as follows. The initial response is a rapid depolarization by an excitatory postsynaptic potential (EPSP), which is mediated by two different types of excitatory receptors for glutamate (AMPA and NMDA). If sufficient excitatory synapses are activated, the threshold for the generation of an action potential (stippled line) may be reached. Meanwhile, collateral fibers also activate GABAergic interneurons. These release GABA on to the principal neuron after a short delay (feed-forward inhibition). The GABA activates both GABA_A and GABA_B receptors, which activate Cl⁻ and K⁺-selective ionophores, respectively. Both actions hyperpolarize the neuron, thereby ensuring that the membrane potential returns toward the resting level and prevents the overexcitation of the PN. If the PN fires an action potential (AP), this is transmitted down its axon (stippled arrows). Axon collaterals excite GABAergic interneurons, which feed back on to the PN and inhibit it (feedback inhibition). The insert shows the response to a single afferent stimulation following pharmacological blockade of the GABA receptors. The synaptic excitation is no longer curtailed and also recruits voltage-dependent ionic conductances in the membrane. This gives rise to a large depolarization surmounted by a number of action potentials, which is reminiscent of epileptic activity.

particularly prevalent in the cerebral cortex, where they serve to synchronize the firing of cortical pyramidal neurons into columnary activity.

Brain–Gut Interactions

Gastrointestinal Disorders and the Influence of Stress

Conclusion

Glossary

<i>Amygdala</i>	A walnut-shaped brain structure that plays a key role in fear.
<i>Atropine</i>	An anticholinergic drug.
<i>Bombesin</i>	A peptide important in various activities both in brain and other organs.
<i>Brain-derived neurotrophic factor (BDNF)</i>	A protein important for maintaining function in various brain areas.
<i>Cholecystokinin (CCK)</i>	A hormone produced by the mucosa of the upper intestine that stimulates contraction of the gallbladder.
<i>Cholinergic</i>	Liberating, activated by, or resembling the physiologic action of acetylcholine.
<i>Functional dyspepsia</i>	A nonorganic disorder typified by stomach discomfort and pains that can not be explained by organic changes.
<i>Gastrin</i>	A polypeptide hormone secreted by the pyloric mucosa that stimulates the pancreas to release pancreatic fluid and the stomach to release gastric acid.
<i>Helicobacter pylori</i>	A family of gram-negative bacteria whose members are spiral shaped, showing corkscrewlike motility; they are found in the vast majority of patients with peptic ulcer.
<i>Hippocampus</i>	A ridge that extends over the floor of the descending horn of each lateral ventricle of the brain.
<i>Histamine</i>	An amine derivative of histidine that is widely distributed in human tissues.
<i>Hypophysectomy</i>	Surgical removal of the pituitary gland.
<i>Inflammatory bowel disease (IBD)</i>	A group of organic disorders of the bowel, including ulcerative colitis and Crohn's disease.
<i>Interferon</i>	A protein that is produced by intact animal cells when they are infected with viruses; it acts to inhibit viral reproduction and to induce resistance in host cells.

Interleukins

Any of a class of proteins that are secreted mostly by macrophages and T lymphocytes and induce growth and differentiation of lymphocytes and hematopoietic stem cells.

Irritable bowel syndrome (IBS)

A functional (nonorganic) disorder characterized by discomfort and pain in the bowel.

Ischemia

Localized anemia as a result of obstruction of the blood supply or to vasoconstriction.

Neuropeptide Y

A polypeptide released by axons at the synapse; it may act as a neurotransmitter and have a direct effect on synapse function or as a neuromodulator, having a long-term effect on postsynaptic neurons.

Neuroticism
Nonsteroidal anti-inflammatory drugs (NSAIDs)
Nonulcer dyspepsia (NUD)
Oxytocin

A neurotic condition, character, or trait.
Drugs that are widely used for the treatment of inflammatory disorders (such as rheumatoid arthritis) and other painful conditions.
Functional dyspepsia.

Peptic ulcer

A polypeptide hormone secreted by the neurohypophysis that stimulates contraction of the uterine muscles.

An ulcer involving the mucosa, submucosa, and muscular layers of the stomach or duodenum, due in part at least to the action of gastric acid–pepsin juice.

Rapid eye movement (REM) sleep

The part of the sleep cycle during which the eyes move rapidly, accompanied by a loss of muscle tone and a low-amplitude encephalogram recording.

Sacral nerves

Any of five pairs of spinal nerves in the sacral region that innervate the muscles and skin of the lower back, lower extremities, and perineum and branch to the hypogastric and pelvic plexuses.

Serotonin

A compound derived from tryptophan that functions as a local vasoconstrictor, plays a role in neurotransmission, and has pharmacological properties.

Sigmoid colon

The S-shaped portion of the colon between the descending colon and the rectum.

Somatostatin

A peptide secreted by the hypothalamus that acts primarily to inhibit the release of growth hormone from the anterior pituitary.

Vagotomy

An operative procedure involving cutting of the vagus nerve, previously used in treatment for ulcers.

Vagus nerve The tenth cranial nerve, forming an important part of the parasympathetic system and carrying information in both directions between the brain and the periphery.

The functions of the gut encompass ingestion, digestion, absorption, and transport of ingested materials through the gastrointestinal (GI) tract. Digestive processes rely on the presence of acid and enzymes to break down the nutrients into individual molecules that can be absorbed across the intestinal lining for passage into the bloodstream. At the same time, the mechanical and chemical means to digest food particles also represent potential threats (aggressive factors) to the integrity of the gut mucosa. If the stomach lining secretes more hydrochloric acid than needed, it has the potential of irritating the duodenal and gastric lining, thus enhancing their sensitivity. Other aggressive factors include nonbeneficial bacteria (in particular *Helicobacter pylori* in humans) and our tendency to self-treatment with NSAIDs. Such a self-digesting potential is prevented by protective factors: (1) the secretion of protective mucus from various mucus glands throughout the GI tract, (2) the secretion of bicarbonate in saliva to remove hydrogen ions, and (3) a high rate of cell regeneration. Endogenous prostaglandins are important for the proper function of these protective factors, as is also an adequate mucosal blood flow. Various stressors are able to modulate all of these functions. Because many effects appear to be stressor-specific and indeed species-specific, several generalizations must be made in what follows.

Brain-Gut Interactions

For stress to impact the GI system, pathways must be in place to permit a bidirectional communication between the central nervous system (CNS) and the gut. Such mechanisms include both nerve pathways and the endocrine system. Among the former are parasympathetic vagal connections terminating in the enteric nervous system, which comprises two plexuses, or networks of neurons, embedded in the wall of the GI tract; the outermost collection of neurons, called the myenteric (or Auerbach's) plexus; and the innermost group of neurons, called the submucosal (or Meissner's) plexus. Included in the latter are the sympathetic innervations via the spinal cord. Among the hormonal influences are epinephrine, adrenocorticotrophic hormone (ACTH), cortisol, and thyrotropin-releasing hormone (TRH). In addition, several immune-system substances (as interferon and interleukins) are now known to impinge on the GI tract.

Secretions

Gastric acid secretion is regulated by an interplay of several neural (cholinergic), hormonal (gastrin), and paracrine (histamine and somatostatin) mechanisms, where histamine is a potent inducer of acid secretion. TRH acts in the brain to stimulate gastric acid, pepsin, and serotonin secretion. TRH is also involved in mechanisms regulating mucosal blood flow, contractility, emptying, and activation of the parasympathetic outflow to the stomach, which may produce gastric ulcerations. Both vagotomy and atropine block this effect. It would appear that the main sites of TRH action in the brain for these effects lie in the dorsal vagal complex, nucleus tractus solitarius, nucleus ambiguus, and the dorsal motor nucleus of the vagus, which receive direct input from the amygdala and indirect input from the ventral hippocampus. Other centrally acting peptides shown to increase gastric secretion include CCK, gastrin, and oxytocin, whereas somatostatin inhibits the secretion of gastrin and histamine and appears to have a direct inhibitory effect on parietal cells.

Centrally acting corticotropin-releasing hormone (CRH), on the other hand, stimulates sympathetic activity while inhibiting parasympathetic activity. Injected into the paraventricular nucleus, CRH reduces acid secretion while increasing bicarbonate secretion. These central effects of CRH are independent of the hypothalamic-adrenocortical axis and vagal activity, but are prevented by adrenalectomy and noradrenergic blocking agents, suggesting that they are mediated by sympathetic outflow. CRH also inhibits the development of stress-induced gastric ulcerations. Apart from somatostatin, other peptides and proteins shown to inhibit gastric acid secretion include bombesin, neuropeptide Y, interleukin-1, platelet activating factor, and the opioid peptides.

Paradoxically, therefore, the immediate effect of central neuroendocrine stress-related peptides appears to be an inhibition of gastric acid secretion. Although the renowned Stewart Wolf and Harold Wolff studies from 1947 on the fistulated patient Tom suggested gastric hypersecretion in response to anxiety, resentment, and hostility, they also noted a transitory hyposecretion during situations associated with overwhelming despair and dejection. Results from animal studies indicate that acute stress is associated with a hyposecretion of acid followed by a hypersecretion (a rebound effect).

Mucus production is also inhibited by stress. The underlying mechanism for this effect appears to be related to the capacity of adrenal steroids to block the prostaglandin synthesis necessary for mucus production within the mucous epithelial cells, as well as

modulating both gastric vasodilatation necessary for adequate circulation and hydrogen ion (H^+) release from the parietal cells. Of the other protective factors, CRH and stress promote bicarbonate secretion but reduce blood flow, leaving the mucosa at risk for focal ischemia. Conversely, Filaretova et al. suggest that corticosteroids may act to maintain gastric blood flow during stress.

The overall picture therefore suggests an acute response to stress of closing down the upper GI system to allow redistribution of energy resources to the organs involved in fight-or-flight behavior. Both human and animal data, however, point to the possibility of local rebound processes in the wake of this acute response. Because the various response systems (e.g., acid secretion, mucus secretion, and blood vessel constriction) do not necessarily follow the exact same time course, a rebound-related increase in acid secretion without the simultaneous reinstatement of adequate blood supply and mucus secretion represents a potential danger to the mucosal integrity.

Gastrointestinal Motility

GI motility is controlled by the reflex receptive relaxation mediated by vagal inhibitory fibers and endocrine influences. Perceived emotional stressors such as fear generally result in acute decreases in gastric motility and gastric emptying, evoked dysrhythmic gastric myoelectrical activity, and increases in colonic activity. These effects are mimicked by CRH and blocked by its antagonists. Pathways for these effects are believed to include higher brain functions that provide descending information to the gut via vagal and sacral nerve pathways rather than via the hypothalamo-adrenocortical axis. Motility is under the influence of several transmitters, most attention being focused on serotonin. Selective serotonin reuptake inhibitors (SSRIs) have proven effective in treatment of motility disorders.

Stomach The majority of mammalian animal studies (rats, mice, dogs, and guinea pigs) indicate that acute stress of various types (shock, avoidance, noise, and handling) leads to a delay in gastric emptying associated with reduced contractile activity or a series of slow contractions outlasting the stress period. It is important to take into account the nutrient content and nature of the meal (acoustic stress delays emptying but only with nutritive meals bulk) and the time course of events (cold increases gastric motility in rats, but this is followed by a decrease). The effects of stress in rat stomach are mimicked by the central application of CRH, which can be blocked by both vagotomy and norepinephrine antagonist drugs.

Early human studies suggested both increases and decreases in gastric motility in response to anger and resentment. Later studies have more consistently shown reduced motility in response to a number of stressors (cold pain, painful transcutaneous stimulation, and noise).

Small intestine The stomach connects the esophagus to the small intestine, and the majority of food digestion takes place here. Stress may alter normal transit time, the gut contents taking longer to travel from the small to the large intestine, and more liquid may be extracted, forming the basis for constipation. This is a potent symptom of the constipated predominant IBS, a functional, nonorganic, pathological bowel disorder.

Large intestine The large intestine is divided into the cecum, colon, and rectum, the cecum making up the first 2 or 3 in. of the large intestine. The colon is subdivided into the ascending, transverse, descending, and sigmoid colon. The last portion of the large intestine is the rectum, which extends from the sigmoid colon to the anus (approximately 6 in.). The nerve supply to the large intestine contains both sympathetic and parasympathetic nerves; sympathetic stimulation inhibits activity and parasympathetic stimulation causes an increase in defecation reflexes. The colon contains the majority of microorganisms in the intestines; these microorganisms weigh more than 1 kg and consist of both friendly and unfriendly bacteria.

Animal studies are fairly consistent in showing increases of colonic motility and colonic transport in response to acute stress or central CRH. The effects of CRH are abolished by noradrenergic blockers but not by adrenalectomy or hypophysectomy. Exposure of rats to psychological stress (as in water-avoidance stress) induces abnormal colonic motility (increased fecal pellet output), enhanced colorectal sensitivity (induced distention), and increased colonic permeability (e.g., urine secretion of 51-chromium ethylenediaminetetraacetic acid).

Gastrointestinal Disorders and the Influence of Stress

Background

The majority of studies have focused on the immediate effects of acute stress on GI function. Clearly, chronic effects of acute stress or effects of chronic stress on GI structure and function will have consequences for illness and disease states.

For decades there has been a clear dissociation in the literature between the functional and organic GI

disorders. The former include functional dyspepsia (FD), (NUD), IBS, and constipation. Organic disorders include peptic ulcer, IBD, cancers, and acute stress ulcer. Traditionally, stress (psychosomatic factors) has been implicated in a number of GI disorders, including gastric and duodenal (peptic) ulcer, gastroesophageal reflux (GERD), and IBS. Apart from the obvious acute effects of stress on the gut, the clinical and epidemiological data support the notion that stress is associated with symptom worsening. A number of reports from war veterans and civilian women indicate high rates of GI symptoms associated with posttraumatic stress disorder (PTSD). However, the relationship between PTSD and the GI system has not received the same research interest as, for example, PTSD's relationship to the cardiovascular system. It is important, as ever, that we be cautious in attributing a disease state to self-reports of prior stress. The presence of abnormal psychological or psychiatric profiles among a patient group does not mean that there is a psychological etiology to the disorder; the psychological changes are at least as likely to be a consequence of the disease (as is suggested for inflammatory bowel disorder). Equally, an absence of psychological/psychiatric abnormalities in a patient group is not sufficient to discard the role of stress in either the onset of the disease process or vulnerability to developing disease symptoms during the life span.

Functional Gastrointestinal Disorders

Patients diagnosed with functional GI disorders (FGID) are frequently reported to have been earlier exposed to severe and/or chronic psychosocial stress and to suffer from emotional disturbances. In recent years, an interest has emerged for studying pain circuits, brain activation, and metabolism (using functional magnetic resonance imaging and positron emission tomography) and neuroendocrine responses to various stressors. There is a consensus that psychological stress plays an important role in patients with IBS in precipitating and/or worsening the symptoms. This has been supported by animal studies of, for example, the long-term consequences of neonatal stress and maternal separation. Induced learned helplessness and chronic mild stress influence subsymptoms such as sleep abnormalities (in REM sleep in particular), production of BDNF, and γ -aminobutyric acid (GABA) receptor activity, which are central to symptoms of depression or anxiety.

Functional dyspepsia FD is a chronic, upper-centered abdominal pain or discomfort characterized by the absence of organic changes that could explain the patient's predominant symptoms, which include nausea, early satiety, vomiting, abdominal distention,

bloating, and weight loss. Nonetheless, some patients may exhibit prepyloric erosive changes of the gastric mucosa that may be confused with acid-induced changes related to gastroesophageal reflux disease (GERD). The role of *Helicobacter pylori* in FD is still under discussion. Although it is not believed to be a cause, testing for and treatment of the infection is regular medical procedure. There is considerable symptom overlap among FD, IBS, peptic ulcer, and GERD. Therefore, a more extended medical examination is often required (e.g., upper intestinal endoscopy). The pathophysiological mechanisms commonly proposed for FD include lowered vagal tone, impaired duodeno-jejunal motility, delayed gastric emptying, impaired gastric meal accommodation, and increased visceral sensitivity in both the stomach and duodenum. The role of stress in the etiology of FD remains unclear and clinical studies show a lack of consistency. Both stress responders and nonstress responders show delayed gastric emptying and increased rates of gastric motility. In addition, psychological profiles and personality traits of FD patients show similar inconsistency although there is some reason to believe that these patients are more prone to seek medical assistance due to general health worries, which may be connected to negative life experiences in early life.

A majority of FD patients presenting to a physician have some psychological or psychiatric abnormality, usually anxiety, mood disorder or neuroticism, or combinations of these, and they also report more adverse life events such as physical and sexual abuse, more relatives with illnesses, and failure to thrive. Personality factors such as trait anger reactivity and neuroticism, coping styles, life stressors, and degree of emotional support are shown to have predictive value in distinguishing among the FGID subgroups. Females with depression, state anxiety, and trait anger temperament are shown to have more FD-like symptoms.

Irritable bowel syndrome Acute studies show that stress increases colonic activity. From the point of view of theories that explain IBS, we are more concerned with accounting for individual differences that can be traced back to earlier stress episodes (i.e., proactive effects). An interesting series of animal studies by Stam has adopted just this approach. A single short series of uncontrollable foot shocks failed to change basal colonic activity in rats but increased colonic activity in response to the presentation of an aversive novel stimulus (shock prod), despite there being no difference in the behavioral response. Such sensitization of the colonic response to a mild (and controllable) stressor after earlier experience with a more severe (and uncontrollable)

stressor provides an attractive model for IBS. Indeed, patients with IBS do report that stressful life events exacerbate their symptoms, and early life stress may be an important contributory factor in the etiology of the disorder. Patients are characterized by higher levels of anxiety, and it is noteworthy that the levels and numbers of shock used by Stam are of the same order of magnitude as those known to induce heightened anxiety in rats. There appears to be an emotional component involved, and there is a gender difference, in that women are affected more than men across all age groups. In addition, there are ethnic differences, in that whites and Jews seem to be more affected than other ethnic groups.

The data are highly suggestive of a link between sexual abuse and later development of IBS symptoms. Twice as many IBS patients report a history of sexual abuse than the normal population, suggesting a sensitization effect of earlier stress on motility function and visceral sensitivity. Closer analysis, however, has led to the conclusion that sexual abuse is more likely to be associated with health-care use in general rather than to any specific GI disorder. In connection with this, IBS patients exhibit visceral hypersensitivity, although their peripheral pain thresholds are normal or even elevated compared to healthy individuals.

Recent studies with brain imaging techniques have revealed that normal subjects respond to rectal distention with the activation of the arcuate nucleus but that IBS patients do not. On the other hand, IBS patients respond to the same stimulus (or anticipation of it) with the activation of the prefrontal cortex. IBS nonpatients do not differ from normals in terms of psychosocial features, but IBS patients do. This may indicate that stress is not a major factor in the etiology of the disorder but rather in general illness behavior.

Organic Gastrointestinal Disorders

Peptic ulcer From being one of the classic psychosomatic diseases, peptic ulcers (stomach or duodenal lining eroded by stomach acid) have to a large extent been removed from the realm of stress-related disorders. The impetus for this radical change was the discovery that the overwhelming majority of patients harbored *H. pylori* and that the elimination of this particular bacterium was almost 100% successful in curing the disorder. A number of issues remain unresolved, however. The incidence of *H. pylori* in the population (50–80% in the older population) is considerably higher than the incidence of peptic ulcer (2–10% lifetime prevalence). The association between the disease and the infection is weaker for gastric peptic ulcer than for duodenal ulcer, as is the efficacy of the eradication treatment. *H. pylori* alone is therefore not sufficient to cause the disease. Other

putative factors include smoking, heavy drinking, and use of NSAIDs. There is considerable evidence from prospective studies that stress is also involved in both the onset and development of the disease. Several studies of groups exposed to chronic stress (e.g., prisoners-of-war and air traffic controllers) also provide evidence for the role of stress. Given the presence of *H. pylori*, it has been suggested that stress acts through the neuroimmune system to modify the rate of colonization of the bacteria. In the absence of the bacteria, it is suggested that peptic ulcer may develop from acute stress ulcerations. The role of *H. pylori* should not be underestimated in also having a potential role in slowing the healing process.

Inflammatory bowel disease IBD is a collective term that refers to both ulcerative colitis (UC) and Crohn's disease (CD). UC involves the inflammation of the mucosal lining of the large intestine, whereas CD may cause the inflammation of the lining and wall throughout the GI tract. The cause of IBD is not known, but there are several theories that combine genetics, immunology, and bacterial and neonatal factors. There is general agreement that UC and CD are not related to stress in any etiological manner; instead, the psychological symptoms associated with these disorders are the result of the poor quality of life in these patients, and stress may induce or exacerbate symptoms of the already existent disease state. Treatment programs focus on assessing possible stressors that may influence healing. Studies show that patients with active symptoms are more likely to report stressful experiences than patients with a more quiescent disease state. Some individuals are especially prone to symptom flare-ups and rehospitalization. Flare-ups of inflammation are reported to be elevated when the affected patients experience unpredictable or uncontrollable stress. The susceptibility to reactivate intestinal inflammation appears to be related to CD4 lymphocyte activity.

There are a number of animal models developed for studying the underlying interactions between stress and UC. Experimentally induced colitis in rats has been shown to be aggravated and sustained by stress. Animal studies also show that neonatal maternal separation sensitizes adult rats to chemically induced colitislike symptoms in addition to altering the intestinal microflora and disrupting the permeability of the intestine.

Stress Ulcer

All species studied develop gastric mucosal abnormalities in response to severe or chronic stress (see **Ulceration, Gastric**). In humans, the acute gastric ulcer is generally observed after severe physical

trauma such as burns, surgery, sepsis, or injury to the CNS (Cushing's ulcer). The pathological background for these changes is most likely an exacerbation of superficial gastric erosions, caused by a combination of (1) restricted blood supply leading to local ischemia, (2) gastric acid, and (3) changes in gastric motility. There is no evidence that adrenocortical secretions play an aggressive role in this process; instead, the mediating mechanisms appear to be CRH-related sympathetic activation and vagally mediated gastric acid secretion.

Conclusion

Both animal and human studies provide clear evidence that stressors can and do impinge on the GI tract, most clearly at the gastric and intestinal levels. Although historically, many disorders were regarded as multifactorial, with stress as one of many contributory factors, the empirical evidence has been lacking due to methodological difficulties. There is no doubt that stress results from these disorders and that stress may exacerbate symptoms. In the case of the functional disorders, current medical attitudes have been influenced by the patients' visceral hypersensitivity. In the case of ulcer disease, the *Helicobacter* revolution has largely excluded a role for psychological stress factors. The basic physiological and psychobiological data together with comparative studies, however, clearly support the older notion that stress has an important contributory role in the etiology and maintenance of these multifactorial disease states.

Evidence Supporting Gender Differences in Stress Responses

Basic Mechanisms of Sexual Differentiation of Neural Function

Clinical Implications for Gender Differences in Stress Responses

Glossary

<i>5α-Dihydro-testosterone (DHT)</i>	Androgen responsible for the masculinization of the genitalia during development. It is metabolized from testosterone by the enzymatic actions of 5 α -reductase.
<i>α-Fetoprotein</i>	A protein produced by the liver. α -Fetoprotein can bind circulating estrogen and sequester it from the brain.
<i>Activational actions of sex steroids</i>	The actions of estrogens and androgens that occur transiently, in direct response to the presence of hormone. Activational effects can occur at any time during life.
<i>Aromatase</i>	An enzyme belonging to the P450 family of enzymes. Aromatase is primarily responsible for the metabolism of testosterone to estrogen.
<i>Critical period of sexual differentiation</i>	The period of time when the central nervous system is most sensitive to the organizing actions of sex steroids. The timing and length of the critical period can vary depending on the species, parameter, and hormone examined.
<i>Estrogen</i>	The main class of sex steroid hormones found in females. Estrogen is produced predominantly in the ovary; however, it can be produced <i>de novo</i> in other tissues and even in brain tissue in both women and men.
<i>Organizational actions of sex steroids</i>	The actions of estrogen and androgen that result in permanent changes in the structure or function of the brain. Organizational effects result from exposure during development or during a period of high sensitivity to the hormone in question.

Testosterone

The main class of sex steroid hormone found in males. Testosterone is produced predominantly by the testis; however, circulating testosterone is also found in females. Testosterone is metabolized to estrogenic as well as androgenic products.

Evidence Supporting Gender Differences in Stress Responses

Gender Differences in Adrenal Function

The early work of Hans Selye described adrenal gland function and its role in homeostasis. This work also provided the first compelling evidence for potential sex differences in stress responses. In supporting the observations of Selye, many studies showed that the adrenal gland is larger in females than in males, even when corrected for sex differences in body weight. Correspondingly, the rate of hormone secretion by the adrenal gland differs between males and females. Moreover, some studies in rodents reported that females show a greater diurnal fluctuation in corticosterone or cortisol, the main steroid hormone secreted by the adrenal cortex (corticosterone in the mouse and rat, cortisol in the hamster and human; [Figure 1](#)). Similarly, the adrenal response in secreting these glucocorticoid hormones following stressful, or perceived stressful, situations such as exposure to noxious fumes, exposure to a novel environment, immobilization, or a brief electric shock (see [Glucocorticoid Negative Feedback, Glucocorticoids, Effects of Stress on, Glucocorticoids – Adverse Effects on the Nervous System, Hippocampus, Overview](#)) resulted in peak elevations in adrenal glucocorticoid hormone levels that were 1.5–2 times greater in females than in males.

In adult animal models, sex differences in adrenal function appear to be relatively confined to glucocorticoids because gender differences in other adrenal cortex-derived steroid hormones, such as progesterone and androgen, have not been reported in the literature. Androgen and progesterone are secreted predominantly by the gonads at relatively high levels. Therefore, gonad-derived steroids may mask any sex differences in adrenal-derived steroids, which may underlie the absence of these types of studies in the literature.

Figure 1 Schematic representation of the hypothalamic-pituitary-adrenal (HPA) axis. The positive feedback portion of the HPA starts at the level of the paraventricular nucleus of the hypothalamus. Neurons residing in this nucleus release corticotropin-releasing hormone (CRH) and vasopressin into the hypophyseal portal vessels to the anterior pituitary to stimulate the synthesis and release of ACTH. This in turn stimulates both synthesis and release of adrenal glucocorticoids into the general circulation to elicit an appropriate stress response. The presence of increased levels of glucocorticosteroids in turn induces an inhibitory effect (i.e., negative feedback) on the HPA axis, which is thought to be mainly mediated through glucocorticoid-responsive neurons in the hippocampus.

Sex Differences in Neuroendocrine Function

Pituitary hormone secretion The sex difference in adrenal function is in part due to sex differences in the neuroendocrine axis that regulates adrenal hormone secretion. This axis has been termed the hypothalamic-pituitary-adrenal (HPA) axis because of the interaction of each of these tissues in regulating one another's secretory activity (Figure 1). Similar to sex differences in the adrenal glucocorticoid release, adrenocorticotrophic hormone (ACTH) is also released in a sexually dimorphic fashion. ACTH is a hormone secreted by the anterior pituitary gland into the general circulation, which in turn stimulates adrenal synthesis and secretion of glucocorticoids. Animal studies also demonstrated that the increases in circulating ACTH levels following physical or psychological stressors are greater and more prolonged in females than in males. An enhanced ACTH response in female

rodents seems to depend on the hypothalamic peptide called corticotropin releasing hormone (CRH), suggesting that the sex difference in ACTH response may, in part, be the result of a sex difference in anterior pituitary responsiveness to CRH.

Hypothalamic function The secretion of ACTH from the anterior pituitary is controlled by hormones that are synthesized in neurons residing in the paraventricular nucleus of the hypothalamus (PVN). These hormones are released into the hypophyseal portal vasculature via the median eminence (Figure 1). The most important releasing factors for ACTH appear to be CRH and vasopressin. Both CRH and vasopressin are potent ACTH secretagogues, and vasopressin potentiates the ACTH-releasing activity of CRH several-fold. Animal studies have shown that the PVN in females contains more CRH neurons than in males. Moreover, females exhibited a more pronounced diurnal variation in hypothalamic CRH immunoreactivity than males. These data are consistent with physiological data demonstrating a greater activation of the HPA axis in females.

Studies have demonstrated sex differences in the release of vasopressin following a stressor. Indeed, vasopressin was released in female rats following immobilization stress, whereas this was not the case in male rats. Although, vasopressin immunoreactivity in the PVN is not sexually dimorphic, the presence of a sex difference in the functional sensitivity of vasopressin cells in the PVN to stressors may help explain sex differences in neuroendocrine responses.

Negative feedback regulation The stimulatory limb of the HPA axis (CRH, vasopressin, and ACTH) is kept in check by continuous feedback inhibition by circulating glucocorticoid hormones. Thus, it has been hypothesized that the intensity of this negative feedback action may be an underlying factor in the sexually dimorphic secretion of adrenal glucocorticoid hormones. The negative feedback glucocorticoids is mediated by two receptor types – mineralocorticoid receptor (MR) and glucocorticoid receptor (GR) – that reside in target neurons in the hypothalamus, hippocampus, and anterior pituitary gland, as well as other brain areas. Both receptors appear to be involved in differing aspects of the negative feedback regulation. Because of their high affinity for glucocorticoids, MRs are thought to regulate basal hormone secretion, whereas GRs, which exhibit a lower affinity for glucocorticoids, are thought to return stress-responsive elevations in glucocorticoids back to baseline. Assuming that the number of receptors accurately reflects the sensitivity of a tissue for a hormone, it is logical to conclude that sex differences in the HPA axis may

result from a sex difference in the number of receptors in a given cell. A greater negative-feedback sensitivity would be indicated by more receptors and consequently result in lower basal and stress-activated hormone secretion. On the other hand, lower levels of receptors would indicate weaker negative feedback and thus result in higher basal and stress-responsive hormone secretion. This hypothesis has been supported by sex differences in the concentration and function of MRs and GRs. Overall, females tend to have lower levels of MRs and GRs in many brain regions, including the hypothalamus and hippocampus, which is consistent with the pattern found in other tissues, such as the thymus and liver. Given similar levels of hormone, GR- or MR-mediated functions (e.g., autoregulation of the receptors) was reported to be less sensitive to glucocorticosteroid modulation in females than in males.

Sex Differences in Behavioral Responses to Stress

Sex differences in behavioral responses to stress have been well-documented in humans and animals. Laboratory animals have provided much of what we know regarding gender differences in response to stress. When placed in a given stressful situation, animals undergo a series of well-described behaviors that have been interpreted to indicate the degree of fear or anxiety that is being experienced. Freezing, defecation, and vocalization are a few good examples of these behaviors. Females appear to be less sensitive to stress-associated novel or aversive environments. For example, when placed into a novel environment or an elevated plus maze, female animals show less freezing and defecation than males. Females also enter a compartment in which they have been previously shocked more readily. In these behavioral paradigms, females also show more activity and exploration, behaviors that have been interpreted as signifying a lesser expression of fear and anxiety. However, when exposed to a variety of chronic stress paradigms, females are found to habituate significantly less than males.

In a well-studied animal model of chronic stress known as learned helplessness, animals are subjected to a repeated inescapable stressor, such as an intermittent tail shock. Subsequently, when allowed to escape, male rats are impaired in their escape performance, whereas female rats do not show this deficit to the same extent. However, when stressed repeatedly over a long period of time, it appears that males adapt more readily (eventually do not show reduced activity), whereas females fail to adapt over the same time period. It appears that this sex difference in adaptability may be dependent on levels of glucocorticoids because the reduction of the poststress glucocorticoid

levels in females to levels attained in males allows the adaptation to repeated restraint. However, these effects are not always observed across studies. One reason may be related findings from studies showing that both strain and stress exposure during early development are important determinants in the expression of stress-related sex differences in behavior in adulthood.

Basic Mechanisms of Sexual Differentiation of Neural Function

Sexual differentiation of the brain occurs as a result of the presence of gonadal steroid hormones acting during either development or adulthood ([Figure 2](#)). The actions of gonadal steroid hormones on the brain have been classified as being either organizational or activational. Organizational actions are permanent changes in brain structure or function that occur during development. Generally, these permanent effects of gonadal steroid hormones are greatest during a defined critical window of opportunity, usually during gestation or early postnatal life. The removal of gonadal steroid hormones after this critical period does not alter the organization or function of the brain appreciably. In contrast, the activational effects of gonadal steroid hormones are those that occur transiently, in direct response to the presence of a gonadal steroid hormone. Indeed, the removal of gonadal steroid hormones from the circulation, through castration or ovariectomy, results in a loss of effect. The activational effects of gonadal steroid hormones can occur throughout life, but are generally thought to have a maximal influence on gender differences during adulthood.

The literature regarding sexual differentiation of the brain suggests that the mammalian brain is an undifferentiated or perhaps neutral state and that, in response to normal circulating levels of testosterone (from the fetal male gonad), it develops toward the male direction. In contrast, if testosterone is low or absent, the brain develops toward the default mode, which is female (see [Figure 2](#)).

Although testosterone or its androgenic metabolite DHT may play a role in the masculinization of the brain, through their intracellular androgen receptor, in rodent models the functional gonadal steroid hormone for the organizational sexual differentiation of the brain is considered to be estrogen ([Figure 2](#)). This steroid hormone is produced intracellularly as a metabolite of testosterone due to the actions of the enzyme aromatase. The defeminizing effects of estrogen on the developing brain are mediated by estrogen receptors (ERs), although the exact role of each of the two forms of ERs, ER α and ER β , is not known.

Figure 2 Schematic representation of the gonadal steroid hormones involved in the sexual differentiation of the vertebrate brain during development. According to this scheme, α -fetoprotein sequesters circulating estrogen, thereby preventing the defeminization (or masculinization) of the male or female brain. Therefore, the brain is thought to be initially programmed to develop in the female direction. However, α -fetoprotein is bypassed in the male brain because circulating testosterone is converted intraneuronally into estrogen by the enzyme aromatase, thus enabling estrogen to defeminize (or masculinize) the male brain, which is mediated through estrogen receptors. AR, androgen receptor; DHT, 5 α -dihydrotestosterone; E, estrogen; ER, estrogen receptor.

Circulating estrogen from the mother or the developing ovary of the female is bound to a liver-derived protein called α -fetoprotein, which is present in high levels during perinatal development. Consequently, circulating estrogens are sequestered and cannot defeminize (or masculinize) the developing male or female brain. In contrast, defeminization (or masculinization) by estrogen can occur in the male brain because the estrogen-sequestering abilities of α -fetoprotein are circumvented due to its intracellular origin through the aromatization of testosterone. In rodents, the high levels of α -fetoprotein decrease during the second and third weeks of life, which coincides with increasing levels of unbound estrogens in the circulating, thus allowing the organizational and activational effects of estrogens to occur at puberty and in adulthood.

Organizational Effects of Gonadal Steroid Hormones on Stress Responses

Gonadal steroid hormones may act during early development to permanently organize adult responses to stress. This is best illustrated by examining the effects of perinatal hormone removal and replacement on the development of the adult pattern of behavior in response to stress. An example is the earlier described sex difference in the performance

of the elevated plus maze and open-field test, in which female rats showed more activity and were less anxious than male rats. Indeed, the activity of an adult male rat that was castrated postnatally (a procedure that removes circulating levels of testosterone and its associated metabolites, such as estrogen) is similar to that of a female rat. The castration of male rats up to 21 days after birth prevents the development of the sex difference in activity. In contrast, neither the castration of adult males nor estrogen or testosterone replacement affects the sex difference in the level of activity. Similarly, the treatment of female rats with testosterone or estrogen up through 4 weeks after birth, but not in adulthood, results in a more malelike activity pattern. These studies indicate a critical period of sensitivity for the organizing actions of gonadal steroid hormones; moreover, they also show that sex differences in the activity level do not arise until after puberty.

Few studies have examined the occurrence of similar organizational effects of sex steroids on neuroendocrine responses to stress. The neonatal gonadectomy of male rats produces a more female-like hormonal response to stress in adulthood, but much of this may be due to the absence of hormones in adulthood because adult gonadectomy has a similar effect. On balance, it appears that the predominant effects of gonadal

steroid hormones on neuroendocrine stress responses are activational in nature, with organizational influences contributing a much more modest amount to the overall sex difference.

Activational Effects of Gonadal Steroid Hormones on Stress Responses

The activational effects of gonadal steroid hormones on stress responses can be demonstrated easily by the gonadectomy of males and females in adulthood. The castration of male rats results in an increase in stress-responsive ACTH and corticosterone secretion. Similarly, the ovariectomy of female rats results in a decrease in stress-responsive HPA axis activity. These are gonadal steroid hormone-specific effects because they were reversed by the replacement of gonadal steroid hormones to gonadectomized animals. Moreover, androgen and estrogen have opposing actions in regulating stress-responsive hormone secretion. The treatment of gonadectomized male and female rats with estrogen augments subsequent ACTH and corticosterone responses to stress, whereas treatment with testosterone, or the nonaromatizable androgen, DHT, effectively inhibits HPA axis responses to stress. These studies provide a good mechanistic understanding as to why the stress-responsive hormone secretion is greatest in female rats during proestrus, when estrogen levels are highest.

Testosterone and estrogen can limit or augment the ACTH and corticosterone response to stress at several sites. These include the adrenal gland, anterior pituitary, hypothalamus, and higher brain centers such as the hippocampus. Receptors for androgen and estrogen exist in all these tissues, and the effects of estrogen and androgen on cellular parameters relevant to HPA activation have been demonstrated in all tissues.

At the level of the adrenal gland, estrogen has been shown to increase the adrenal secretory response to ACTH administration. Similarly, some studies showed that in the presence of estrogen the anterior pituitary gland responds to CRH with a greater secretion of ACTH than in the absence of estrogen. Increases in CRH immunoreactivity and mRNA have also been demonstrated in the hypothalamus in response to estrogen treatment. Whether these are direct actions on CRH neurons or mediated transsynaptically is currently in question. However, studies have demonstrated that the promoter sequence of the human CRH gene contains sequences (estrogen response elements) that respond to occupied estrogen receptors by increasing gene transcription, suggesting a direct action on the CRH gene. More recently, studies in rodents and humans showed the presence of ERs in some populations of CRH neurons of the PVN.

Similarly, androgen also appears to act at several sites. Castration increases adrenal enzyme activity and the synthesis of corticosterone by the adrenal gland *in vitro*, suggesting that testosterone acts to inhibit adrenal activity. Although testosterone does not appear to alter the anterior pituitary ACTH response to CRH administration, it does decrease CRH immunoreactivity in the hypothalamus of castrated rats. A direct action of testosterone on CRH synthesis or secretion does not seem to be the case because CRH neurons do not contain androgen receptors; thus upstream sites containing androgen receptors and projecting to CRH cells in the hypothalamus have been implicated, including the medial preoptic area, septum, and bed nucleus of the stria terminalis.

Sex differences in circulating estrogen and testosterone are also responsible for the sex differences in brain GR and MR levels or function. These effects underlie the reported sex differences in the negative feedback modulation of the HPA axis. Estrogen decreases GR and MR levels and their respective mRNAs in some brain areas and interferes with the ability of GR to autoregulate gene expression following changes in circulating glucocorticoids. These effects of estrogen could arise secondarily as a result of estrogen-induced increases in corticosteroid-binding globulin (CBG). In response to estrogen exposure, increased levels of CBG can sequester circulating glucocorticoid hormones from the brain, resulting in a decrease in negative feedback. However, estrogen has also been reported to increase GR in some tissues, such as the pituitary gland, and decrease the efficacy of corticosteroid receptor agonists that are not bound by CBG. Thus, it is likely that the actions of estrogen on the negative feedback are not solely mediated by an increase in CBG.

At the molecular level, interactions between ERs and GRs have been demonstrated with each modulating the functional response of the other. Testosterone also appears to interact with glucocorticoids in the regulation of GRs, but not MRs; however, a clear role for androgen receptors in altering negative feedback mechanisms has yet to be demonstrated.

Clinical Implications for Gender Differences in Stress Responses

Hans Selye's work in the 1940s also introduced the concept that stress accelerates the onset of disease through pathophysiological changes in endocrine and autonomic regulatory systems. Stress alone does not cause disease, but it is hypothesized to increase an individual's susceptibility to disease. In the past quarter century, this concept has been supported by results from numerous clinical and epidemiological studies

related to cardiovascular disease, affective disorders, gastrointestinal disorders, diabetes, and physiological disorders associated with normal aging.

The mechanisms linking stress to disease states in humans are not fully understood, but hormonal changes, induced by the stress response, are recognized as a major influence. Glucocorticoids have a primary role but one that is modulated by gonadal steroid hormones. Androgen receptors, ERs, and GRs are found in many tissues that are stress-responsive. Some of these include the heart muscle, blood vessels, and immune tissues such as the spleen, thymus, and bone marrow. Gonadal steroid hormone receptors are also found in brain regions that mediate emotional and autonomic responses to stress, such as the hippocampus, hypothalamus, and amygdala. Thus gender differences in stress-related disease susceptibility appear to involve an interaction between glucocorticoid and gonadal hormones.

The role of stress in psychological and physiological disorders is complex. Animal studies have demonstrated that adult stress responsiveness is influenced developmentally by both genetics and the early environment. This bidirectional influence of both factors makes it difficult to predict the stress-related susceptibility to disease in individuals. However, physiological gender differences are still evident in humans regardless of early environment.

Many of these differences parallel sex differences in animals. For instance, the unstressed basal heart rate in women is greater than in men. Women also exhibit a larger exercise-induced increase in heart rate. However, in response to anger and psychological stress, men exhibit greater emotional and cardiovascular lability with respect to both heart rate and blood pressure. This lability, resulting in larger increases in systolic pressure, is thought to contribute significantly to the greater risk in men for cardiovascular morbidity. Protection from heart disease in women is also related to estrogen, which provides protection against arteriosclerosis until menopause. The anti-atherosclerotic effects of estrogen also appear to involve the presence of ERs in cardiovascular tissue.

Physical or psychologically stressful stimuli also produce a greater stimulation of the HPA axis in women than in men, similar to the stress effects observed in other mammals. Administering CRH to women induces a greater release of ACTH and a prolonged elevation of cortisol than administering it to men, indicating that these gender differences probably involve processes directly under the regulation of the central nervous system. However, unlike animals, gender differences in the human HPA axis responsiveness to psychological stressors appear to be

much more dependent on the type of psychological stress and the environmental circumstances in which it occurs. Studies suggest that psychological factors associated with social stress, such as taking care of an elderly parent, have more impact on HPA reactivity in women than in men, perhaps placing women's health at greater risk under such circumstances.

A primary factor underlying gender differences in the HPA response to stress appears to be higher estrogen levels in women. During the normal menstrual cycle, HPA activity is enhanced during the follicular phase, when estrogen levels peak, and is reduced during the luteal phase, when progesterone levels are elevated. The removal of the ovaries prior to menopause reduces the HPA sensitivity to CRH stimulation. The effect of estrogen on HPA reactivity is not gender-specific because normal men who were administered a short-term regimen of estrogen also exhibited increased HPA activity. One possible explanation for such effects of estrogen is provided by observations that estrogen therapy increases circulating levels of CBG in women. Although not yet shown to be the case, such increases in CBG, and the resulting decreases in free cortisol, could play a role in the elevated HPA activity in response to stress reported in women (due to a decrease in cortisol bioavailability). Similarly, it remains to be determined whether men and women are equally sensitive to the influence of estrogen on the HPA and whether organizational influences of gonadal steroids confer a differential sensitivity to the later hormonal modulation of HPA activity.

The incidence of autoimmune disease is also sexually dimorphic, and the severity and onset are exacerbated by life stress. The overall incidence in women is approximately 2.5-fold greater than in men. In contrast to the protective role estrogen plays in cardiovascular disease, it appears to be a major contributory factor to the gender difference observed in autoimmune diseases such as multiple sclerosis, rheumatoid arthritis, and lupus. Estrogen can regulate immune responses through ERs present on thymocytes, macrophages, and endothelial cells, all of which also express GRs. The interaction between estrogen and glucocorticoids on immunomodulation is a rapidly expanding area of research interest and one that is likely to underlie the gender difference in autoimmune disease susceptibility.

Numerous clinical studies have reported a greater incidence of depression in women. The reasons underlying this gender difference are controversial, but both hormonal status and stress may be involved. Women have been reported to be more susceptible to depression during periods of fluctuations in estrogen and progesterone levels. However, although such

changes have often been cited as causes of mood disorders in women, the literature does not provide strong support for a direct causal relationship between gonadal hormone status and depression or anxiety disorders. An additional mediating factor may be life stress. The onset of clinical depression is well known to be exacerbated by life stress, and data suggest that a link to a gender bias in mood disorders involves an increased susceptibility in some women to the combined effects of stress and hormonal status. Thus, fluctuations in estrogen and progesterone during the menstrual cycle have been proposed to confer a susceptibility to depression in women that can be exacerbated by life stress.

A gender difference is also observed in the incidence of posttraumatic stress disorder (PTSD), which is a stress-induced pathological condition that is clinically distinct from depression or other affective disorders. Long-term physiological changes are observed in PTSD patients that involve increased adrenergic tone and alterations in HPA function. Following exposure to prolonged psychological trauma, women exhibit PTSD symptoms twice as frequently as men, even when the type of trauma is equivalent. The organizational effects of hormones may also play a role in gender differences in the incidence of PTSD. This stems from findings showing that experiencing psychologically traumatizing events prior to puberty greatly increases the susceptibility to PTSD in adulthood in females compared to males. This increased susceptibility appears to relate specifically to experiencing childhood psychological trauma because accidents or injury during this period do not increase the risk for PTSD in either gender when later psychological trauma is experienced.

In summary, current research studying the interrelationships among gender, stress, and pathophysiology strongly implicate a role for gonadal hormones in predicting gender differences related to disease or psychopathology. However, a definitive understanding of the role of gender in the elicitation of stress-induced pathophysiology awaits a better understanding of the complex relationship among the environment, steroid hormones, and other stress-induced biochemical factors.

Quantitative Genetics

Molecular Genetics

Behavioral Genomics and GE Interplay

Future QTL Research on GE Interplay

Glossary

<i>DNA pooling</i>	A molecular genetic technique that combines DNA from individuals in order to estimate allele frequencies for the group of individuals.
<i>Family chaos</i>	A measure of the family environment derived from the Confusion, Hubbub, and Order Scale.
<i>Genotype–environment correlation (rGE)</i>	Genetic influence on exposure to environments.
<i>Genotype–environment interaction (GxE)</i>	Genetic sensitivity to environments.
<i>Microarray</i>	A technology that allows the genotyping of hundreds of thousands of polymorphisms simultaneously.
<i>Quantitative genetics</i>	The statistical study of the genetic and environmental origins of individual differences in complex traits, using information about the relatedness of individuals; in contrast to molecular genetics, which attempts to identify specific genes.
<i>Quantitative trait locus (QTL)</i>	A genetic polymorphism that plays a role in the etiology of a trait influenced by many such loci.
<i>Single nucleotide polymorphism (SNP)</i>	A genetic polymorphism involving the substitution of a single letter (nucleotide base pair) of the four-letter genetic alphabet.

The interplay between nature and nurture has long been characterized as adversarial; the truth is much more complex, and more interesting. Although there are many ways of thinking about the issue, this article considers genotype–environment (GE) interaction and correlation from a quantitative genetic

perspective, where GE interaction refers to genetic sensitivity to environments and GE correlation refers to genetic influence on exposure to environments. Diathesis-stress theories predict that individuals' sensitivity to stressful events and access to social support networks depends on their genotype. Although evidence for such interactions is – as yet – inconclusive, a more convincing case can be made for genetic influence on environmental measures: gene–environment correlations. The ability to detect gene–environment interplay has traditionally relied on the use of specific environmental measures in genetically sensitive designs such as twin or adoption studies. This ability is greatly enhanced by incorporating genotyping for specific genes: new methods for doing this are likely to see future stress research making use of genetic measures as a matter of course.

Quantitative Genetics

Over the past two decades, there has been an increasing tendency to include measures of the environment in quantitative genetic research; without measures of the environment, quantitative genetic designs such as twin and adoption studies cannot contribute much to our understanding of GE interaction and correlation. This section begins with quantitative genetic research on GE interaction and correlation that incorporates measures of the environment and then turns to molecular genetic research that incorporates information from DNA. The effects of stressful environments on learning ability and disability are used as an example of how molecular genetics can contribute to our understanding of gene–environment interplay.

GE Interaction

The great advantage of research with animal models is the ability to manipulate both genes and environment experimentally so that main effects and interaction are assessed directly. That is, genetically different animals such as selected low and high lines or inbred strains can be studied in different environments. Animal models are powerful, but they have been hard-pushed to find GE interaction, especially for learning. The classic example in psychology textbooks is Cooper and Zubek's study of maze-bright and maze-dull rats reared in enriched or deprived environments. However, although it is highly cited, its conclusions are doubtful: Henderson studied GE

interaction systematically using inbred strains of mice and found few such effects.

Adoption designs are similar to animal designs, except that they are only quasi-experimental in their separation of genes and environment (Figure 1). Parents usually share both genes and environment with their offspring, but adoption separates nature and nurture by creating a distinction between genetic parents whose children are adopted away and environmental parents who adopt these children. Using the phenotype of biological parents as an indicator of genetic risk and the phenotype of adoptive parents as an indicator of environmental risk, we can find genetic effects without environmental effects (Figure 1a) and environmental effects without genetic effects (Figure 1b). Studies usually reveal both genetic and environmental effects (Figure 1c). The adoption design can also identify GE interaction (Figure 1d), in which genetic effects depend on environmental effects or vice versa. However, as with animal studies, it has been difficult to find GE interaction, especially for cognitive abilities. Twin studies are much more limited in terms of finding GE interaction because they are essentially constrained to detecting differences in heritability as a function of the environment.

For example, in the Twins Early Development Study (TEDS) of a large twin sample assessed at 2, 3, 4, and 7 years, GE interaction was looked for,

but not much evidence for it was found using quantitative genetic methods. Despite this, one promising example of GE interaction is that heritability of verbal ability is significantly higher (about 0.60) in high chaos families and lower (about 0.30) in low chaos families. However, the twin design lacks power to detect even this limited type of GE interaction: about 1000 pairs of each type of twin are needed to detect a heritability difference of 60% versus 40%. As discussed later, the lack of quantitative genetic evidence for GE interaction does not preclude the likelihood that molecular genetic research will find interactions between specific genes and specific environmental stressors.

GE Correlation

In spite of the current interest in GE interaction, it is likely that GE correlation, the nature of nurture, will eventually be seen as more important. Animal models are powerful for investigating GE interaction, but laboratory research has rarely considered GE correlation because it requires a menu of environments from which individuals can choose. The first step in addressing GE correlation is to investigate the extent to which there is genetic influence on environmental measures. This can be done by treating environmental measures as dependent measures in quantitative genetic analyses. Dozens of such twin and adoption

Figure 1 G, E, and GxE in an adoption study. G refers to low or high genetic risk, as indexed by the phenotype (quantitative trait [QT]) of the biological parents. E refers to the environment of the adoptive home. a, A main effect of G, but no effect of E on the phenotype. b, A main effect of E, but no effect of G. Very often, there is a main effect of both G and E, as illustrated in c. d, A main effect of both G and E, and a GxE interaction of the diathesis stress type, in which environmental risk (stress) has a disproportionately large effect on individuals at genetic risk (diathesis).

studies consistently find genetic influence on environmental measures: nearly all measures of family environment show genetic influence. Most studies that have addressed this question find genetic influence on environmental measures outside the family as well, such as peer groups, life events, and social support, which are of particular relevance to stress.

How can environmental stressors show genetic influence when environments do not have DNA? The answer is that our measures of stress are not independent of us – genetic influence on our behavior is reflected in our experiences. If genetics affects both environmental measures and behavioral measures, then the correlation between environmental measures and behavioral outcomes may be genetically mediated. Life events such as illness and injury have been shown to have a heritability of around 40%, implying that they do not happen capriciously to individuals: they happen, or are perceived to happen, more often to the genetically predisposed. As expected, those life events that the individual is involved in or has control over show more substantial heritability than those that happen to others. Recent research suggests that minor, chronic, daily stressors may be more important in determining outcomes than major life events. New studies are expected to show that these also show genetic influence. In a similar way, social support networks show heritability: studies have demonstrated that although the extensiveness of the network is not heritable, the quality of the relationships is.

The method underlying all these studies is to use multivariate genetic analysis to analyze genetic and environmental sources of covariance between environmental stressors and behavioral outcomes. Studies of this sort consistently show some genetic mediation of the association. In this sense, quantitative genetic research provides much more evidence for GE correlation than for GE interaction. GE correlation suggests an important model of environments that goes beyond the usual passive view in which the environment (and, by extension, stress) is what happens to us. Instead, environments are active: we select, modify, construct and, afterward, reconstruct our experiences partially based on our genetic propensities. From a molecular genetic point of view, GE correlation means that we ought to be able to find specific genes associated with environmental measures.

In summary, quantitative genetic research does not find much evidence for GE interaction, but it finds considerable evidence for GE correlation. This section has not gone into great detail because quantitative genetic results on GE interaction and correlation are not very relevant for future research in this area, which will use specific genes as well as specific

environments. The rest of this article considers molecular genetic approaches.

Molecular Genetics

So far, evidence of the existence of interplay between genes and the environment has been considered. Research on GE interaction and correlation will be much more powerful when we are able to include specific genes as well as specific environments, that is, when the G in GE refers to genes in molecular genetic analyses rather than genotypes in quantitative genetic analyses. There have been several replicated linkages and associations, but most people would agree that progress has been slower than expected in terms of finding genes for complex behavioral traits. The problem is that we are looking for needles in a haystack, but we have only had the power to detect very large needles. Very rarely, the effects of a single gene can account for all the variance in a trait. This is the case with phenylketonuria (PKU), in which a mutation in both copies of a single gene results in the inability to metabolize the amino acid phenylalanine. This causes a buildup of toxic products that damage the developing brain. The environmental intervention of a low phenylalanine diet has the effect of preventing mental impairment in children with PKU but has no effect on other children: a dramatic example of a GE interaction.

Despite the slow progress in identifying quantitative trait loci (QTLs) associated with common disorders and complex traits, some evidence has been found for GE interaction using candidate QTLs that affect genetic sensitivity to environments. For example, there are reports that the influence of maltreatment in early life on the development of adult antisocial problems is moderated by a functional polymorphism in the promoter region of the *MAOA* (monoamine oxidase A) gene. Likewise, the influence of stressful life events on depression may be moderated by a functional polymorphism in the promoter region of the *5-HTT* (5-hydroxytryptophan [serotonin] transporter) gene. These examples of GE interaction emerged despite the absence of a main effect for these two genes.

For the vast majority of complex traits, the largest QTL effect is unlikely to account for more than 1% of the variance. Very large samples are needed to attain power to detect such small effects, and even larger samples are needed to detect GE interaction. Rather than just examining a few candidate genes, the trend in molecular genetic research is toward systematic genome-wide scans that require hundreds of thousands of DNA markers. The costs for such genome-wide association scans on very large samples are substantial.

One new method that goes some way to solving this problem is genotyping of pooled DNA on microarrays, a method called SNP-MaP (single nucleotide polymorphism microarrays and pooling).

The first application of SNP-MaP involved mild mental impairment (MMI), which can be seen as the low end of general cognitive ability (g). g was assessed in 10 000 children at 7 years, and two independent SNP-MaP studies using a microarray that assessed 10 000 SNPs (the 10K GeneChip) compared high and low g groups. Five SNPs were identified that remained significantly associated with g when individually genotyped for 5000 children. On average, each SNP in the set accounts for just 0.2% of the variance in g . However, as the effects of the SNPs are uncorrelated and additive, it is possible to combine their effects to create a composite SNP set using an additive model in which each SNP is scored 0, 1, or 2, depending on the number of high- g -associated alleles. The SNP set accounts for nearly 1% of the variance of g scores at 7 years. As shown in Figure 2, SNP set scores are normally distributed and almost linearly related to g . The difference between those scoring low on the SNP set and those scoring high is about one-third of a standard deviation, or 5 IQ points.

Repeating the analysis using the newly available 500K microarray should find many more SNPs accounting for much more of the variance. It will then be possible to use SNP set scores as genetic risk indicators in research into environmental stressors and to select genotypically for extreme SNP set groups to use

in paradigms such as neuroimaging that cannot study large samples.

Behavioral Genomics and GE Interplay

Once genes or QTL sets associated with behavioral dimensions or disorders are found, the next phase of research will investigate the pathways between genes and behavior via the brain, which will represent a paradigm shift in research on GE interplay. The term functional genomics, which has been used to describe this direction for research, usually refers to bottom-up research that begins with understanding the gene product in a cell and works up toward the brain and behavior. However, other levels of analysis can also be useful in understanding pathways between genes and behavior: behavioral genomics refers to a complementary approach that begins with behavior of the individual and works down toward the brain. For example, we can investigate how genetic effects unfold during development or ask multivariate questions about heterogeneity and comorbidity. As the present concern is GE interaction and correlation, the focus will be on behavioral genomic analyses of GE interplay.

To return to the earlier example, the 5-SNP set associated with g at 7 years was used in behavioral genomic analyses of GE interaction and correlation. The environmental measures employed in these analyses included distal environmental measures such as parental occupation or education and proximal measures such as family chaos and discipline in early

Figure 2 Distribution of 5-SNP g set and association between 5-SNP set and 7-year g . The distribution of scores for the SNP set (derived on the basis of higher scores for high- g -associated alleles) is normal (gray bars). The line represents the means of the 5-SNP set score plotted against means of the g composite score at 7 years.

childhood in those homes. Although GE interaction can be examined in several different ways, the extent to which environmental stressors moderate the SNP set association with *g* was investigated. Using family chaos as an example, the top panel (a) of Figure 3 shows a main effect for family chaos (higher *g* scores

for children in families with less chaos) but no statistically significant interaction using linear and nonlinear continuous analyses.

The other three environmental variables shown in Figure 3 yielded significant but modest GE interaction. For harsh parental discipline (Figure 3b),

Figure 3 *g* scores as linear and nonlinear functions of SNP set scores and level (low, medium, and high) of environmental risk for chaos (a), harsh parental discipline (b), father's occupational class (c), and mother's highest qualification (d). Ninety-five percent confidence intervals (dotted lines) are shown for low and high levels of environmental risk.

environmental effects are greater at both the high and the low SNP set scores. For high SNP set scores, children with good environments (low harsh discipline) have higher than expected g scores, whereas children with low SNP set scores and harsh parental discipline have lower than expected g scores. In other words, this GE interaction suggests that children with a genetic propensity toward high g profit disproportionately from a good environment, and children with a genetic propensity toward low g suffer disproportionately from a bad environment. A similar sort of GE interaction was found for father occupation (Figure 3c): environmental effects were greater at both the high and the low genetic extremes.

We also found a significant GE interaction for the fourth environmental measure, maternal education (Figure 3d). However, this GE interaction represents a different sort of interaction, one that is compatible with recent findings from quantitative genetics suggesting that genetic effects on g are weaker for families with lower socioeconomic status. The result for maternal education is compatible with this finding: the association between SNP set and g is weakest for families with the least-educated mothers.

What about GE correlation? As noted earlier, GE correlation refers to the correlation between genes and environment. In contrast to GE interaction, which concerns environmental moderation of the association between the SNP set and g, GE correlation focuses on the extent to which the environment mediates the association between the SNP set and g. Such mediation requires that the environmental measure correlate with the SNP set and also correlate with g. Because the environmental measures were chosen for their correlation with g, the simplest GE correlation analysis was conducted, which was merely to correlate the environmental measures with SNP set scores, rather than conducting more formal mediation analyses. Both proximal measures of the family environment (harsh parental discipline and family chaos) were correlated significantly with the SNP set for g, suggesting GE correlation. It is interesting that the distal measures of family environment (father's occupation and mother's education) showed no GE correlation. Of the three types of GE correlation (passive, evocative, and active), finding GE correlation for distal environmental variables would be most easily characterized as passive GE correlation: the children's family environments would be correlated with their genetic propensities because their parents share the same genes. In contrast, these analyses suggest that GE correlation is stronger for proximal environments, implying evocative (reactive) GE correlation: children evoke reactions based on their genetic propensities.

In summary, there is evidence for both GE interaction and GE correlation in early development. One final caveat is that GE interactions may result from GE correlations under certain circumstances; true GE interaction should remain significant after controlling for GE correlation.

Future QTL Research on GE Interplay

In addition to using QTLs identified on the basis of their main effect in order to investigate GE interaction and correlation, future research on GE interplay will profit from identifying QTLs that contribute to GE interaction and correlation regardless of their main effect. In the previous example, SNPs were identified based on their association with g (regardless of environment) by comparing SNP allele frequencies for low versus high g groups. Figure 4 shows a simple two-by-two interaction design in which cases are selected based on low versus high environmental stress as well as on low versus high g. Using DNA pooled separately for the four groups, QTL associations representing the main effect of the QTL on g regardless of environment stressors can be detected by comparing groups 1 and 2 versus groups 3 and 4. The important advantage of this design is that GE correlation and GE interaction can also be detected independent of their contribution to the main effect. GE correlation can be assessed as the main effect of the environment, comparing groups 1 and 3 versus groups 2 and 4, thus identifying QTLs that are associated with low versus high environmental stress. Finally, GE interaction can be detected by comparing the diagonals (groups 1 and 4 versus groups 2 and 3).

The future of research on genotype-environment interaction and correlation looks bright, especially as the G in GE increasingly comes to represent genes in molecular genetic analyses rather than genotypes in quantitative genetic analyses.

Low g	1	2
	3	4
High g		
		Low E High E

Figure 4 Identifying QTLs on the basis of GE interaction and correlation. Using four, rather than two, DNA pools will facilitate these studies. For example, comparing SNP allele frequencies for pools 1 and 2 versus pools 3 and 4 tests for a main effect for g. Comparing pools 1 and 3 versus 2 and 4 reveals GE correlation, a QTL association with E. Comparing pools 1 and 4 versus 2 and 3 assesses GE interaction, a QTL association for g that depends on E.

Genes Regulating the Stress System
Stress Effects in Prokaryotes and Eukaryotes
Summary

Glossary

- Allele** Alternative forms of a gene at a given locus.
- Apoptosis** Programmed cell death inducible by DNA damage that exceeds the capacity of repair mechanisms.
- Chaperone** Any protein that binds to an unfolded or partially folded target protein, thus preventing misfolding, aggregation, and degradation of the target protein and facilitating its proper folding.

<i>DNA polymerase</i>	The enzyme responsible for replication of DNA, which is accomplished by using each complementary strand of the DNA double helix as a template for the synthesis of a new strand.
<i>Epistasis</i>	The situation in which expression of one gene obscures the phenotypic effects of another gene.
<i>Fitness</i>	A measure of fertility and therefore of the contribution to the gene pool of the succeeding generation; for a given genotype, the number of offspring surviving to reproductive age is relative to the number of wild-type genotypes.
<i>Genotype</i>	The genetic constitution of an individual or the alleles at specific genetic loci.
<i>Heavy chain-binding protein (bip)</i>	A protein discovered by its interaction with the heavy chain of IgG antibodies in the endoplasmic reticulum, keeping proteins unfolded and preventing misfolding.
<i>Homology</i>	Similarities between newly derived sequences and previously determined sequences.
<i>Intron</i>	A segment of a gene that is initially transcribed into RNA but is then removed from the primary transcript by splicing together the exon sequences on either side of it; intronic sequences are not found in mature mRNA.
<i>Phenotype</i>	The observed result of the interaction of the genotype with environmental factors.
<i>Pleiotropy</i>	The diverse effects of a single gene or gene pair on several organ systems and functions.
<i>RNA primer</i>	A short RNA sequence that is paired with one strand of DNA and provides a free 3' OH end at which a DNA polymerase starts the synthesis of a deoxyribonucleotide chain.

Stress is the response of the cell or the organism to challengers of homeostasis (a dynamic state of balance between the stress response and the stressors). Homeostasis is essential for the preservation of life. In humans and other higher organisms, components of the stress system include various neurotransmitters and hormones, which in most species constitute the effectors of the hypothalamic-pituitary-adrenal (HPA) axis. Thus, the cholinergic and catecholaminergic systems, corticotropin releasing hormone (CRH), arginine vasopressin, adrenocorticotrophic hormone (ACTH), and the glucocorticosteroids are all essential parts of the stress system in higher organisms.

At the cellular level, the major players are different but still analogous to the effectors of the HPA axis: the DNA repair system, the heat shock proteins (hsp), and the products of many housekeeping genes that

aim at maintaining homeostasis. In order to find genes that have a role in the regulation of the stress system in humans, it is essential to look at the effects of stress at all levels of development. This article reviews the effects of stress on various systems and notes the role of genetics in each one of them.

Genes Regulating the Stress System

Genetic loading can be described as follows. An individual with large innate susceptibility needs only a minor degree of internal or external stressors to reach the threshold for symptom expression and vice versa. The prevalence of psychosomatic symptoms among members of the same family suggests the existence of a genetic predisposition. When the fingerprints of 155 adult patients with psychosomatic abdominal pain since childhood were examined for congenital markers, digital arches were found in 64% of patients, compared to 10% of controls without abdominal pain. Genetic factors play an important role in the pathogenesis of psychiatric illnesses. The location of potential genes of interest for manic-depressive/bipolar disorder, a state of profound stress, has been summarized by Wahlstrom.

Role of the Corticotropin Releasing Hormone Gene and Other Components of the Hypothalamic-Pituitary-Adrenal Axis

CRH plays a key role in the regulation of the stress response with the CRH receptor type-1 (CRH-R1) as mediator. CRH-R1 is highly expressed in the anterior pituitary, neocortex, hippocampus, amygdala, and cerebellum. The activation of this receptor stimulates adenylate cyclase. CRH-R1-deficient mice show an impaired stress response as indicated by the absence of increased ACTH and corticosterone levels following stress.

Although acute and long-standing internal or external conflicts/stressors predispose to depression, a state associated with stress and elevated glucocorticosteroid levels, the CRH gene on human chromosomal region 8q13 is not linked to manic-depressive/bipolar disorder. Other components of the HPA axis have also been tested for linkage. On chromosome 5, the glucocorticoid receptor gene and the genes for β_2 - and α_1 -adrenergic receptors were excluded as candidates for manic-depressive disorder based on parametric lod score analyses. Mutation analysis in the gene for the adrenocorticotrophic receptor located on chromosome 18p11.2 was negative. In addition, parametric methods of analysis excluded the area of the proopiomelanocortin gene on chromosome 2 for linkage to bipolar disorder.

Role of the Tyrosine Hydroxylase Gene

Another component of the stress system is the catecholaminergic system. Tyrosine hydroxylase (TH) catalyzes the rate-limiting step in catecholamine synthesis. The TH gene is regulated by an array of biochemical mechanisms in response to environmental factors. In animals, a long-term increase of TH activity can be elicited by electrical stimulation and environmental stress or drugs such as reserpine. In humans, the involvement of the TH locus in manic-depressive disorder is supported by association studies. However, the precise genes with a causative role in bipolar disorder are not yet known. It is possible that a particular variant of the tetrarepeat located in the first intron of the TH gene plays a role. Studying mechanisms of regulation of TH gene expression in rats showed the existence of stressor specificity and stressor-specific pathways. In rats exposed to cold or insulin stress, adrenal denervation (splanchnectomy) prevented a rise in adrenal medullary TH mRNA levels, whereas immobilization-induced stress led to an increase in TH mRNA levels, suggesting that genetic changes in TH may indeed affect the stress response.

Role of Dopamine Receptors

The main effects of dopamine on the central nervous system include locomotion and behavior. Forebrain dopamine systems are involved in mediating the behavioral effects of chronic mild stress. At present, five subtypes of dopamine receptors are known and are classified as D1-like and D2-like, according to their similarity to the first and second cloned receptor. D1-like receptors are encoded by intronless genes and D2-like receptor genes are divided by intron sequences, suggesting that dopamine receptors have evolved from two main ancestral genes.

D1 receptors are predominant in the basal ganglia such as the nucleus accumbens and are involved in a prolactin stimulatory pathway in response to high environmental temperature stress. D1 receptor-deficient mice fail to thrive after weaning, with selective impairment of motivated behavior, including drinking and eating. These mice also demonstrated that the D1 receptor is important in drug addiction and reward mechanisms. The role of dopamine D1 receptor actions in reducing the function of the prefrontal cortex (a higher cognitive center) has been shown in various studies, including the infusion of a dopamine D1 receptor agonist in the prefrontal cortex, which induced cognitive deficits similar to those seen in stress. Increased catecholamine receptor stimulation in the prefrontal cortex leads to stress-induced working memory deficits, which can be ameliorated by agents that

prevent catecholamine release or that block dopamine receptors.

Mice lacking D2 receptors have an impaired reproductive function. Alterations of the D3 receptor function may play a role in behavioral disorders associated with hyperactivity, such as attention deficit hyperactivity disorder, a disease of prefrontal cortex dysfunction.

Stress Effects in Prokaryotes and Eukaryotes

Effects of Stress on Life History Traits in *Drosophila*

In natural populations, there may be significant genetic variation for stress resistance and life history traits. Different genotypes may respond differently to environmental stress, and the variation in these norms of reaction may be of great importance to the maintenance of genetic variation in metabolic traits. Each physiological response may be mediated by different genes in different individuals. Similarity between parents and progeny may be altered if the genes that contribute to variation in a trait in one environment do not contribute in another environment. Responses of life history traits to selection may depend on environmental conditions in different ways. Heritabilities for morphological traits are more constant than for life history traits.

Interestingly, selection for stress resistance can alter many traits. In selected lines of *D. melanogaster* undergoing stress, including starvation, heat, radiation, and ethanol and acetic acid exposure, a decrease in metabolic rate, early fecundity, and early behavioral activity, as well as an increase in male longevity, occurred. In *D. simulans*, desiccation resistance was associated with resistance to starvation and toxic ethanol. In *D. serrata*, selection for desiccation resistance also resulted in an increased resistance to starvation. When *D. melanogaster* and *D. simulans* were selected for increased cold intolerance, cross-generational effects were detected in all lines with marked effects of selection on early fecundity. Selected lines in both species showed reduced fecundities specifically associated with the selection response.

However, not all responses to stressful conditions are associated with correlated changes in life history traits. For instance, selection for increased knock-down resistance to heat in *D. melanogaster* led to lines that were two- to fivefold more resistant to this stress. This selection response did not alter life history traits and was associated with allelic changes in two heat shock genes, suggesting that such genes may

have specific effects on stress resistance and do not necessarily have life history costs.

These findings show that responses to stress can have many secondary effects unrelated to stress. Organisms under permanent stressful conditions may be expected to show life history changes that reduce their fitness under more favorable conditions. Many trait values seen in natural populations may reflect the effects of infrequent stressful conditions. The overall fitness of an individual that is unable to survive an infrequent stress will be zero, regardless of performance under normal conditions. The complexity of pleiotropic effects and epistatic interactions contribute to the likelihood that genotype and environment interactions play an important role in the maintenance of genetic variation.

Effects of Stress on Phenotype

In animals, most populations experience at least sporadically stressful conditions and change drastically in size when studied over long intervals. Environmental changes such as sudden climate changes can have many indirect effects, including competitive interactions and susceptibility to diseases. Animals developed many mechanisms for coping with sudden environmental shifts. For example, rapid changes at the cellular level involving the synthesis of enzymes and heat shock proteins occur in response to most stresses. Extreme conditions can influence the expression of phenotypic variability and the extent to which this variability is determined genetically. For instance, in *D. melanogaster* stress can produce abnormal morphological characteristics when the flies are exposed to stresses early in their development. However, the experimentally induced extreme conditions used to generate these mutant phenotypes probably do not exist under field conditions, and the resulting morphological peculiarities such as ultra-bithorax in *Drosophila* would probably not survive in nature.

Effects of Cellular Stress on Genotype

Genetic variants may result from the ability of cells to repair damaged DNA or from the limited accuracy of the cellular machinery for DNA replication. By means of the fluctuation test, Luria and Delbrück attempted to clarify whether bacterial mutants arise spontaneously or specifically in response to a particular kind of stress. They concluded that genetic variants do originate randomly and without selective pressure. However, the possibility that, in addition to spontaneous mutants, genetic variants might have been induced by selective pressure was not excluded

in that experiment; it was investigated and confirmed by Cairns in 1988. The degree of variation between parents and progeny differs enormously with different forms of life, depending on the stability of the living conditions.

Under nonstress conditions, variants predominantly result from replication errors. Eukaryotic organisms possess four (yeast, and probably other lower eukaryotes) or five (higher eukaryotes) different DNA polymerases. Cells do not need to assure a high accuracy of RNA primer synthesis because mistakes occurring during primer synthesis do not contribute to the mutation rate. Cells possess a battery of enzyme systems for DNA repair to avoid the loss of integrity of DNA genomes. The DNA repair system evolved to restore the original status of the damaged genome structure and to improve the ability of the cell to survive. However, some of the DNA repair processes are error-prone and are therefore important sources of genetic variants. In response to DNA breaks, recombination–repair mechanisms may construct a genome in an order that is different from the original. A cell will, naturally, rather survive as a variant than be killed as the original. Repairing DNA under the condition of prolonged stress may induce more genetic variants than absolutely necessary, as shown in starving bacterial cells that developed induced replication-independent mutants of selective advantage in the face of inhibited proliferation and threatened survival of the population. During severe stress, multiple mutations occur at high rates in cells that survived the hypermutable state with extensive DNA damage.

Effects of Stress on Heat Shock Gene Regulation and in Human Disease

Heat shock proteins: history Heat shock proteins were first described in 1962 when the chromosomes of the giant salivary gland of *D. busckii* were exposed to an elevated temperature that resulted in areas of swelling on the chromosome known as puffs. These puffs indicated transcriptionally active genes that were found to belong to the hsp family. The hsp are called molecular chaperones because they bind to unfolded proteins and thereby prevent the aggregation and misfolding of these proteins during cell stress.

Over the following years, stress protein research attracted the attention of basic and clinical investigators in many disciplines. Among other topics, studies on stress proteins include gene expression and the complex signal transduction pathways that control the regulation of stress genes; other studies focus on the role of stress proteins as molecular chaperones that regulate various aspects of protein folding and

transport and on the role of stress proteins in human disease.

Heat shock proteins: function Via the heat shock response as a homeostatic mechanism, cells are able to survive exposure to extreme environmental stress. Thermally induced stress proteins can also protect cells against other stresses that themselves induce stress protein synthesis. Such cross-protection is known as cross-tolerance.

The elevated synthesis of a few proteins following exposure to heat or other stressful stimuli, including ischemia; anoxia; hypoxia; cytokines; and certain drugs such as vasopressin, isoproterenol, and calcium channel blockers, occurs in all organisms ranging from prokaryotic bacteria such as *Escherichia coli* to mammals, including humans. After the genes encoding these stress proteins had been cloned, other genes encoding related stress proteins were identified based on their homology. Subsequently, many stress proteins were found to be encoded by multigene families encoding proteins with similar but distinct features. Major eukaryotic stress proteins are usually referred to as hsp with a number that reflects the molecular mass in kilodaltons, for example, hsp70 (Table 1).

Based on their molecular mass, the hsp are subdivided into two groups: large and small hsp. Small hsp possess a domain of homology to α A,B-crystallin proteins from the vertebrate eye and are less conserved than large hsp. Small hsp caught the attention of researchers because these proteins are able to induce protection against various toxic chemicals and interfere with inflammatory mediators. Cell death usually occurs by two distinct processes: necrosis and apoptosis. Small hsp protect cells against stress-induced necrosis and can also prevent differentiating cells

from apoptosis. Therefore, small hsp participate in essential physiological processes in unstressed cells. There are at least 4 major small hsp in *Drosophila*, 3 in mammalian cells and yeast, and more than 20 in plants. Although small hsp in plants are represented by at least two multigene families, the small hsp27 in humans is encoded by a single gene located on chromosome 7.

There seems to be a link between small hsp expression and tumorigenicity. Several cancer cell lines, including breast cancer, were found to show changes in the expression of mammalian hsp25/27. Small hsp expression is also considered a prognostic parameter of some human tumors. For instance, in patients with breast cancer or osteosarcoma the expression of hsp27 is associated with a poor outcome.

Many of these stress proteins are also expressed in normal, unstressed cells, indicating that the function of hsp is likely to be required in normal cells but more so in stressed cells. Because this function has been conserved in evolution, it seems to be very important in all cells ranging from bacteria to humans. A large body of evidence shows that the primary role of the majority of hsp is creating the proper folding of other proteins in order to enable these proteins to fulfill their appropriate functions. Stressed cells produce aberrant proteins that are folded improperly and sometimes too abnormal to be refolded properly. For such situations, some stress-inducible proteins, such as the hsp ubiquitin, are involved in protein degradation.

Among the first genes that are transcribed from the embryonic genome are genes encoding stress proteins such as hsp90, emphasizing the importance of the complex regulatory processes of the stress proteins in normal and stressed cells.

Table 1 Eukaryotic stress proteins

Family	Member	Functional role	Comment
Ubiquitin	Ubiquitin	Protein degradation	In the nucleus found conjugated to histone H2A
Hsp27	Hsp27, Hsp26, etc.	Actin-binding proteins, protein folding	In different organisms very variable in size (12–40 kDa) and number
Hsp47	Hsp47	Protein folding of collagen and possibly other proteins	Homology to protease inhibitors
Hsp56	Hsp56 (=FKBP59)	Protein folding, in the steroid receptor complex associated with hsp90 and hsp70	Peptidyl prolyl isomerase activity, target of immunosuppressive drugs
Hsp60	Hsp60	Protein folding and mycobacterial unfolding, organelle translocation	Major antigen of many bacteria and parasites that infect humans
Hsp70	Hsp70, Hsc70, Hsx70, Grp78 (=Bip)	Protein folding and unfolding, assembly of multiprotein complexes	Hsx70 only in primates
Hsp90	Hsp90, Grp94	Maintenance of proteins such as steroid receptors in an inactive form until appropriate	<i>Drosophila</i> and yeast proteins known as hsp83
Hsp100	Hp104, Hsp100	Protein turnover	ATPase activity, role in tolerance to extreme temperature

The specific transcription factor heat shock factor 1 (HSF1) induces stress protein genes after exposure to heat or other stresses and exists in an inactive (monomeric) form in unstressed cells. The regulation of these stress protein genes in response to nonstressful stimuli or in normal cells remains to be elucidated.

Stress proteins seem to be essential for the survival of cells and organisms. Thus far in mammals there is no knockout mouse lacking specific hsp genes. In *Drosophila* and in yeast, the inactivation of the hsp90 gene turned out to be lethal. However, it is possible that the inactivation of an individual stress protein gene is not lethal in all cases if genetic and functional redundancy are present. If, however, the function of a specific family of stress proteins is completely eliminated, survival is unlikely.

Heat shock proteins and chaperones show specific expression patterns during development and cell differentiation as well as during aging. hsp genes do not act as developmental genes to direct development along one pathway or another. Rather, as important partners in differentiation, cell division, and apoptosis, hsp act at the cellular level to regulate development.

The maintenance of homeostasis in mammals is achieved by many mechanisms, including the release of cytokines in response to stressful challenges. It is well known that, via interleukin-6, tumor necrosis factor α and interleukin-1 activate the HPA axis, including the CRH neuron. Cytokines are redundant and functionally pleiotropic. By activating specific transcription factors that bind and transactivate hsp genes, cytokines are also capable of inducing stress proteins/hsp, such as hsp90, hsp70, and hsp27 (Table 2).

Mild stress, sufficient to induce hsp, could protect cells against a subsequent, more severe stress. Transgenic animals overexpressing hsp70 showed an enhanced resistance to cardiac ischemia. In the clinical setting, studies are underway to identify drugs that could induce the synthesis of stress proteins in a

nonstressful manner and to find ways to deliver stress protein genes to damaged organs *in vivo* using gene therapy procedures.

On the other hand, the enhanced expression of stress proteins may play a role in many different human diseases. Several studies report that the synthesis of stress proteins is induced by stress caused by disease; this appears to be stress protein- and disease-specific. For instance, hsp90 is specifically overexpressed in a subset of patients with systemic lupus erythematosus, whereas the expression of other stress proteins is unaffected. General or specific overexpression of stress proteins can evoke an autoimmune response that leads to the production of antibodies or T cells that recognize these proteins and possibly cause a damaging immune response. Such immune responses to individual stress proteins, especially to hsp60, have been described in rheumatoid arthritis, multiple sclerosis, and diabetes mellitus type 1.

hsp90 is one of the most abundant proteins in eukaryotic cells. It makes up 2% of total cellular protein even under nonstress conditions and is highly evolutionary conserved with homologs in bacteria, yeast, *Drosophila*, and humans. hsp90 is needed for cell survival, as demonstrated by mutation analysis in yeast. hsp90 is important for the function of steroid receptors and perhaps certain viral oncogenic kinases. The hsp gp96, hsp90, and hsp70 isolated from tumors were able to immunize and elicit protective immunity specifically against the tumors from which the hsp were isolated. The hsp isolated from normal tissues were found to elicit immunity to any cancers tested. hsp96 molecules are not immunogenic per se but act as carriers of antigenic peptides. The hsp90 family may be a novel target for anticancer drug development such as vaccines, especially because cancer cells are very sensitive to the pharmacological disruption of hsp90 function.

Exciting work in yeast is centered around conformational alterations in prionlike proteins, which are believed to cause neurodegenerative diseases in humans, including Creutzfeldt-Jacob, mad cow disease, and possibly even Alzheimer's. The delineation of an evolutionary-conserved chaperone related to hsp70 whose expression changes in response to environmental stress has been found to control the inheritance of a yeast prionlike element (release factor Sup35) called PSI. Further studies of this complex non-Mendelian genetic system may elucidate how the cellular response to stress may cause disease.

Summary

Stress, a state of threatened homeostasis, leads to an individual stress response that is subserved by the

Table 2 Candidate genes

Transcription factors	Glucocorticoid receptor, mineralocorticoid receptor, androgen receptor, estrogen receptor, progesterone receptor, aryl hydrocarbon receptor, heat shock factor 1, mutated p53
Protein kinases	Tyrosine kinases (Src family, sevenless, weel, p185), serine/threonine kinase (Raf-1/v-Raf, casein, heme-regulated eIF-2 α , CDK4/CDK6, MEK)
Other proteins	Cytoskeletal proteins (tubulin, actin, intermediate filaments), calmodulin, proteasomes, G-protein $\beta\gamma$ subunit

stress system(s). Each physiological response may be mediated by different genes in different individuals, perhaps explaining why the same/similar internal and external stressors affect individuals in different ways. This is complicated by the complexity of pleiotropic effects and the interactions between genotype and environment that contribute to the maintenance of genetic variation. At the molecular and cellular level, stress evokes the synthesis of enzymes and over-expression of certain genes, many of which encode heat shock/stress proteins. These stress proteins are expressed not only in stressed cells but also in normal cells underlining their essential function. For instance, a functional ubiquitin pathway that helps eliminate damaged proteins in the cytosol, nucleus, and endoplasmatic reticulum is an essential feature of the stress response in eukaryotes as well as of unstressed cells. All cells have multiple ubiquitin genes, each of which encodes a fusion between ubiquitin and another protein. In line with Aristotle's *in medias res* (everything in moderation), it appears that individuals and, at the molecular and cellular level, cells exposed to too much stress or to no stress at all have a shorter longevity than cells and individuals that are coping with mild stress sufficient to induce protective factors such as hsp against subsequent more severe stresses.

Glossary

<i>Allele</i>	One of two or more possible forms of a gene. An individual may possess two identical or two different alleles, except for the genes on the X-chromosome in males (they possess only a single copy of this chromosome).
<i>Body mass index (BMI)</i>	A measure of body fat based on height and weight that applies to both adult men and women.
<i>Case/control studies</i>	Comparisons between groups of individuals with particular features or disorders and groups apparently normal for these aspects; often employed to search for differences in the genotype or allele frequencies between the two groups.
<i>Genotype</i>	The configuration of alleles at a genetic locus. If both alleles are identical the individual is homozygous; if the two alleles differ the individual is heterozygous.
<i>Haplotype</i>	The pattern of alleles at two or more polymorphic sites represented on one of the chromosome homologs.
<i>Intragenic feature</i>	A feature located within the conventional boundaries of a gene.
<i>Kilobase (kb)</i>	One thousand base pairs.
<i>Linkage disequilibrium</i>	The existence of combinations of alleles at two or more polymorphic sites within a region at frequencies greater than expected by random assortment.
<i>Missense mutation</i>	A base change in the coding region of the gene that results in the substitution of one amino acid in the encoded protein for another.
<i>Polymorphism</i>	The existence at gene locus of more than one allele with the rarest at appreciable frequency (usually assumed to be >1%) in the population.

Promoter

The section of DNA that precedes a gene and controls its activity.

Single nucleotide polymorphism (SNP)

A polymorphism at a single base position in DNA.

Stressor

Stimulus input that creates stress and initiates a response.

Genes and the Stress Responses

The genetic basis for the stress response is complex; nevertheless, the genes involved can be divided into two broad categories: those encoding the autonomic reaction to stressful situations and those involved in the neuroendocrine stress response. The typical rapid reactions to perceived stress are well recognized to be associated with the fight-or-flight response and are mostly mediated by the sympathetic nervous system with the release of norepinephrine from widely distributed synapses and epinephrine from the adrenal medulla. Implicit in this classic description of the rapid stress response is the recognition of the potential violent and aggressive outcomes that stress can engender. A more delayed response is mediated by the release of cortisol, the major glucocorticoid in humans. This is initiated by neural signals to the hypothalamus that releases corticotropin releasing hormone (CRH), which in turn results in the release of adrenocorticotrophic hormone (ACTH) from the anterior pituitary, thereby stimulating cortisol production by the adrenal cortex. The production of cortisol assists in restoring homeostasis in response to stress; however, prolonged exposure can be potentially harmful.

Reactions to acute stress are also usually accompanied by perturbations of serotonergic activity, as indicated by altered levels of serotonin (5-HT) or its metabolites. Serotonin is a significant regulator of morphogenetic activities during early central nervous system development, including cell proliferation, migration, and differentiation.

Outcomes following exposure to stress may, therefore, be highly variable depending on a wide range of genetic factors controlling these various aspects. A simplified overview of some of the most important elements of stress response and relevant genes is shown in [Figure 1](#). The significance of genetic variation in the better-characterized components of the stress response pathways is considered next. Several case/control studies have examined the association between genes involved in the stress response and somatic

Figure 1 The stress pathway illustrating selected genes (in bold italics). 11 β -HSD1, 11- β -hydroxysteroid dehydrogenase enzymes; ACTH, Adrenocorticotrophic hormone; GR, glucocorticoid receptor; CRH, corticotropin releasing hormone; DBH, dopamine β -hydroxylase; DDC, DOPA decarboxylase; FKBP5, glucocorticoid receptor co-chaperone; NET1, norepinephrine transporter; PAH, phenylalanine hydroxylase; PNMT, phenylethanolamine *N*-methyl transferase; TH = tyrosine hydroxylase. α - and β -Adrenergic receptors include ADRA1A, ADRA1B, ADRA1D, ADRA2A, ADRA2B, ADRA2C, ADRB1, ADRB2, and ADRB3.

or behavioral traits. Some of these are noted; however, it is important to recognize that there are potential confounding factors to such studies and only consistent replication and supporting molecular evidence can establish the formal verification of such links.

Polymorphisms of Genes in the Autonomic Stress Response Pathway

The rapid stress response to stressful stimuli is mediated by the release of norepinephrine in the brain. This leads to the activation of the sympathetic nervous system and the adrenal medulla with release of epinephrine in the blood. Hence, the genes regulating the biogenesis and degradation of both epinephrine and norepinephrine and those encoding their cognate receptors are key players in the primary stress response. The epinephrine and norepinephrine metabolic pathways share components with those for other neurotransmitters. The steps in the synthesis of epinephrine from amino acid precursors are illustrated in Figure 1. The last two critical steps are undertaken by the enzymes dopamine β -hydroxylase (DBH) and phenylethanolamine *N*-methyl transferase (PNMT).

Dopamine β -Hydroxylase

The dopamine β -hydroxylase gene (*DBH*) is located on chromosome 9. A SNP in the presumed controlling

region of *DBH*, which results in the substitution of a C to T substitution 1021 bp before the transcription start, accounts for up to 50% of the variance in plasma levels of the enzyme. Other variants flanking, or within, the potential promoter region include a polymorphism that depends on the copy number of an intragenic dinucleotide repeat approximately 4 kb upstream of the transcription start and a 19-bp insertion/deletion located 118 bp upstream.

In addition several SNPs have been reported within the coding region. Of these, an arginine to cysteine substitution in exon 11 has been suggested to be the most likely functionally significant variant. Several studies have linked a variation in plasma levels and *DBH* genotypes to various physiological and behavioral disorders, including hypertension, psychosis, depression, migraine, attention deficit hyperactivity disorder, and alcoholism. These reported associations await replication and consolidation.

There are also reports of individuals with undetectable levels of norepinephrine and epinephrine, together with elevated levels of dopamine. Such individuals have low, or absent, circulating DBH enzyme caused by deleterious mutations affecting both copies of the *DBH* gene and manifest a range of symptoms, including orthostatic hypotension.

Although alterations to this key enzyme in the synthetic pathway for norepinephrine and epinephrine

are likely to have significant consequences for the stress response, no specific behavioral or physiological features relating to the reactions to stressors *per se* have been reported.

Phenylethanolamine *N*-Methyl Transferase

The gene for PNMT, a key enzyme, is located on chromosome 17. Two SNPs that may affect the regulation of the gene have been identified in the promoter. When tested in case/control studies, significant association was observed between these and early-onset, but not late-onset, versions of Alzheimer's disease, and there are data suggesting a possible association between these SNPs and hypertension in African American groups. In addition, there is evidence suggesting that a variant of this gene may be associated with blood pressure regulation abnormalities in the stroke-prone, spontaneously hypersensitive rat strain.

Norepinephrine and Epinephrine Receptors

The adrenergic receptors for epinephrine and norepinephrine are divided into two major classes, alpha (subdivided into α_1 and α_2) and beta (subdivided into β_1 , β_2 , and β_3). These receptors are targeted by a variety of drugs, including the so-called beta-blockers; hence genetic variation in them may be an important feature for pharmacotherapy. The activation of the β -adrenergic receptors stimulates adenylate cyclase.

α_1 -Adrenergic receptors The α_1 -adrenergic receptors are G-coupled trans-membrane receptors that are capable of binding both epinephrine and norepinephrine and thereby mediate some aspects of the sympathetic nervous system. The genes encoding them include *ADRA1A* (formerly known as *ADRA1C*, on chromosome 8), *ADRA1B* (formerly known as *ADRA1*, on chromosome 5) and *ADRA1D* (formerly known as *ADRA1A*, on chromosome 20). Of these, *ADRA1B* is of particular interest because fine mapping with highly polymorphic markers localizes it to a region that also contains the dopamine receptor gene *DRD1A*. Because this chromosome region has been linked to variability in systolic blood pressure, genetic variation in either *ADRA1B* or *DRD1A*, or both, may play an important role in influencing interindividual differences in this feature; however, specific functional variants in these have yet been described.

α_2 -Adrenergic receptors The release of norepinephrine is controlled by negative feedback from α_2 -adrenergic receptors, which are located on the presynaptic side of nerve terminals, including nerve muscle junctions. The targets of the released norepinephrine on heart muscle cells (myocytes) are

β_1 -adrenergic receptors. The individual roles of the three highly homologous α_2 -adrenergic receptors (*ADRA2A*, *ADRA2B*, and *ADRA2C*, encoded by genes located in humans on 10, 2, and 4, respectively) have been studied by gene disruption in mice. Both *ADRA2A* and *ADRA2C* subtypes were found to be required for the normal presynaptic control of transmitter release from sympathetic nerves in the heart and from central noradrenergic neurons. In addition, a small deletion (base pairs 322–325) in the *ADRA2C* gene in humans has been shown to decrease function and may act in concert with the beta-receptor gene *ADRB1* as a risk factor for heart attack.

A polymorphism leading to the deletion of three glutamic acid residues from a repeating motif in the third intracellular loop of *ADRA2B* has been associated with variations in basal metabolic rate.

β -Adrenergic receptors β_1 -Adrenergic receptors encoded by the gene *ADRB1* (also known as *ADRB1R*, located on chromosome 10) are present in heart, and their stimulation causes an increase in heart rate. Many beta-blockers act on these targets (and on β_2 receptors to a lesser extent). One variant of the β_1 -adrenergic receptor gene, which changes an arginine at position 389 in the protein to glycine, has been shown to possess increased function in tissue culture. There is also a polymorphic variant of a small deletion (base pairs 322–325) in the gene for the α_2C -adrenergic receptor, *ADRA2C*, that has decreased function. A marked increase in the risk of heart failure among black patients has been observed for those who are homozygous for this and the *ADRB1* variant. This suggests that genotyping of these two genes may be a useful approach for identifying people at risk for heart failure. Further support for an interaction between these two genes has been provided by recent studies indicating that *ADRA2A* and *ADRB1* proteins form heterodimers when expressed in tissue culture cells. In Caucasian women, it has been observed that the arg389 allele of *ADRB1* was associated with greater body weight and BMI.

β_2 -Adrenergic receptor Several polymorphic variants have been described, the most common and significant of which is a substitution causing a change from glycine to arginine at position 16. β_2 -Adrenergic receptor agonist drugs are widely employed in the treatment of asthma. It is therefore of interest that an excess of the glycine allele has been observed in nocturnal asthmatics. It appears that this substitution imparts enhanced agonist-promoted downregulation of the receptor.

A second polymorphism is centered on amino acid 27, where a glutamine to glutamic acid replacement

is observed. An association with obesity has been reported, with an excess of the glutamine version in nonobese individuals. Possible links of this variant with asthma have also been noted.

A third variant involving a threonine to isoleucine replacement at amino acid 64 exists at lower frequencies. This has a profound functional consequence that results in a fivefold reduction in sensitivity to β_2 -receptor agonist-mediated vasodilatation. This suggests a mechanistic explanation of decreased survival in patients carrying this variant.

β_3 -Adrenergic receptor The β_3 -adrenergic receptor, ADRB3, is located mainly in adipose tissue and for this reason has been studied in relation to obesity. A mutation resulting in the substitution of arginine for tryptophan at amino acid position 64 has been observed at a frequency of approximately 10%. Many studies have examined the relationship of the polymorphism to obesity, BMI, and noninsulin-dependent diabetes mellitus, with some concluding that the locus may have a role in predisposing these phenotypes; but other studies have failed to replicate the observations.

Norepinephrine Transporter

The norepinephrine transporter protein 1 (NET1) is also known as the norepinephrine transporter (NAT1) or the solute carrier family 6, member 2 (SLC6A2). The gene responsible is localized on chromosome 16. Approximately 80% of the reuptake of norepinephrine is mediated at nerve terminal synapses by the norepinephrine transporter. SLC6A2 is a target for the tricyclic antidepressants, including imipramine and desipramine and also for amphetamines and cocaine.

Following a report of SNP in the restriction site for the enzyme *TaqI*, a number of detailed investigations have revealed a range of rare mutations associated with orthostatic intolerance and more than 20 polymorphisms, some of which resulted in missense substitutions; however, no association with behavioral disorders were observed in the case/control studies. An insertion/deletion polymorphism of 4 bp in one of several AAGG repeat motifs in the promoter region at a position overlapping a transcription factor binding site has been reported, and there is some evidence supporting an association between the presence of the insertion and restricting anorexia nervosa. Rare genetic variants encoding a transporter with reduced affinity for norepinephrine have also been described. Carriers have been observed to manifest clinical symptoms (orthostatic intolerance) and metabolic evidence for disordered uptake of norepinephrine.

In summary, studies on the genes implicated in autonomic norepinephrine and epinephrine pathways

have demonstrated the potential for a great deal of interindividual diversity. The consequences of this have major impact on a wide variety of disorders, including several with direct or indirect links to stress. Other autonomic pathways are mediated through acetylcholine release and detection.

Polymorphisms of Genes in the Neuroendocrine Stress Response Pathway

Further sources of genetic diversity in individual reactions to stress are the genes implicated in the delayed response of the hypothalamus-pituitary-adrenal (HPA) axis, leading to the release of cortisol from the adrenal cortex initiated by neural signals to the hypothalamus. Other genes are involved in the subsequent mobilization of hypothalamic peptide hormones (including CRH), resulting in the secretion of ACTH from the anterior pituitary and the release of glucocorticoid hormones (cortisol) from the adrenal cortex. Glucocorticoids are produced by the adrenal cortex and restore homeostasis in response to stress; however, prolonged exposure resulting from chronic stressful occurrences is potentially harmful. Cortisol (the most prominent glucocorticoid in humans) or corticosterone (in rats) is largely bound to corticosteroid-binding globulin in the systemic system. It has a classic steroid hormone mode of action via binding to a cognate intracellular receptor (the glucocorticoid receptor) and subsequent migration to the nucleus, where the complex interacts with a specific gene transcription apparatus. The loss or profound diminishment of glucocorticoid secretion leads to a state of deranged metabolism and an inability to deal with stressors, which, if untreated, is fatal. Functional genetic polymorphisms in some important genes of this pathway are recognized.

The Glucocorticoid Receptor

Two specific corticoid receptors are recognized: the glucocorticoid receptor (GR) and the mineralocorticoid receptor (MR). Whereas the latter binds aldosterone and glucocorticoids with similar high affinity, GR is selective for the glucocorticoids. It appears that the main response to raised levels of steroids resulting from stress is mediated primarily by GRs. There have been several polymorphisms described for the GR gene, including one in the promoter region. Because there is strong linkage disequilibrium across the gene, there are relatively few different combinations of allelic patterns, with four major haplotypes recognized. Knowledge of the haplotype may help determine the response to glucocorticoid treatments. Variants

within the coding region include two polymorphisms at adjacent codons for the amino acids 22 and 23 in the protein. Whereas the base change at codon 22 does not change the amino acid (glutamic acid), the polymorphism at codon 23 results in a change from arginine to lysine. Individuals with a specific combination of alleles at the promoter site and the codon 22–23 sites have an associated relative resistance to glucocorticoids. A further polymorphism resulting in a change from asparagine to serine at codon 363 appears to be associated with hypersensitivity to glucocorticoids. A *BclI* restriction enzyme polymorphism has also been employed in case/control studies, and there is evidence for an association with hypersensitivity to glucocorticoids that may be related to lower BMI in older individuals.

A wide variety of membrane-bound GRs have been reported in a range of tissues including the liver, lymphocytes, adrenal gland, and pituitary. There is a paucity of information concerning any structural features distinguishing these various forms, and there are no data on how any genetic variation may affect them, other than through changes affecting the GR itself. Significantly, however, the GR function depends on interactions with several components of a large molecular complex. Five co-chaperones of GR are recognized as significant in regulating its activity, and they are encoded by the following genes:

- *BAG1* – BCL2-associated anthanogene 1
- *STUB1* – STIP 1 homologous and U box-containing protein 1
- *TEBP* – Thyroid transcription factor 1 (TITF1)
- *FKBP4* – FK-506 binding protein 4
- *FKBP5* – FK-506 binding protein 5

A recent analysis of SNPs in these genes found three within the *FKBP5* locus to be significantly associated with the increased recurrence of symptom episodes in depressed patients and a rapid response to prescribed antidepressant treatment. Evidence for this apparent association was strengthened by genotyping a range of additional SNPs within and flanking the gene. One marker in particular (rs1360780) seems to track the tightness of the control of glucocorticoid signaling and HPA axis reactivity mediated by the reported interaction of the GR and *FKBP5*.

11- β -Hydroxysteroid Dehydrogenase Enzymes

Glucocorticoids are metabolized by the 11 β -hydroxysteroid dehydrogenase enzymes (11 β -HSD1). There are at least two forms of 11 β -HSD1: type I (HSD11B1) and type II (HSD11B2). Both catalyze the conversion of cortisol to cortisone; however, the type I enzyme also catalyses the reverse reaction. Both

are therefore important in the stress response. The HSD11B2 enzyme inactivates 11-hydroxysteroids in the kidney, the circumventricular organ of the brain, and some other tissues, thus protecting the nonselective MR from occupation by glucocorticoids. A base change confers a restriction-fragment-length polymorphism (detected by the enzyme *AluI*) in exon 3 of this gene. This variant and a polymorphic microsatellite marker of the *HSD11B2* gene having 12 alleles have been employed to compare salt-sensitive (SS) and salt-resistant (SR) individuals in otherwise nonhypertensive white males. Homozygosity for one of the microsatellite alleles was higher in SS subjects than in SR subjects and the cortisol-to-cortisone ratios were higher in homozygous subjects than in the corresponding control subjects. It is possible that the decreased HSD11B2 activity observed in SS subjects reflects its involvement in the SS blood pressure response in humans and that variants of the gene contribute to different blood pressure responses to salt in humans.

Loci Whose Polymorphisms Interact with Stressful Influences in Mediating Behavioral Outcomes

The Serotonin Transporter

One particularly interesting connection between the perception of stress response and the serotonergic system is through the serotonin transporter, which removes the neurotransmitter from the synaptic cleft. The serotonin transporter (SERT, 5-HTT) plays a pivotal role in brain 5-HT homeostasis. It is also the initial target for both antidepressant drugs and drugs of abuse, some of which are potent neurotoxins. In humans, the gene for the transporter (variously designated as *SERT*, *HTT* or *SLC6A4*) is characterized by functional variants in the promoter region conferring high or low activity in expression of the locus. Several studies have linked variations of the two predominant alleles with anxiety response. Caspi and colleagues were the first to show that it appears that individuals with the low activity are more vulnerable to stressful life events and more likely to become clinically depressed as a result. Glatz and colleagues, in 2003, suggested a possible connection between stress and the serotonin system. They were able to demonstrate that a potent glucocorticosteroid hormone, dexamethasone, stimulates the expression of *SERT* in tissue culture at physiological concentrations. The hormone interacts with the promoter in an allele-specific manner, and this interaction may help to explain the differential vulnerability of individuals who are more susceptible to stressful experiences.

Monoamine Oxidase Type A

A similar picture emerges for variation of another gene involved in the serotonin system, the gene for monoamine oxidase type A, MAOA. Although this enzyme also has a role in metabolizing other neurotransmitters, including dopamine, drugs inhibiting its activity have long been employed in the treatment of behavioral disorders (particularly depression) and are thought to work through altering 5-HT levels. There are two major variants in the promoter of this gene that confer either high or low activity. Because the gene is X-linked, males exhibit either one or the other phenotype without complications from the presence of a second allele. There is a consensus view emerging that males who have the low-activity form of the gene are more sensitive to the effects of maltreatment and presumptive stressful environment manifested by their increased risk of antisocial behaviour and aggression. The high-activity form of the gene appears to provide protection against this outcome.

Conclusion

The response of individuals to stress varies considerably and depends on a wide range of environmental experiences, together with cognitive and genetic factors. Considerable progress has been made in characterizing some of the genes in the pathways relevant both to the fight-or-flight response and to those involved in the release and detection of glucocorticoid hormones. Many of the most significant changes to such genes are rare mutations. There are in addition, however, several variants of genes that are widely distributed in the population, and, although their impact may not be directly observable as an altered stress response, they may have important consequences with respect to a range of complex disorders including hypertension and allergic reactions. Furthermore, recent studies have shown common variants in the key enzymes involved in 5-HT metabolism (MAOA and SERT) can interact with stressful life experience to predispose individuals to manifesting antisocial behaviour or depression. Variants in several other related genes have subsequently also demonstrated an interaction with stress in predicting behavioral outcomes.

How Genes and Stressful Events Can Interact

Measuring Life Events

Twin Studies of Exposure to Stress

Molecular Genetic Approaches

Glossary

Genes

It is estimated the human genome contains approximately 30,000 genes distributed on the 23 pairs of human chromosomes, and about one-third of genes are expressed in the brain. Each gene is the specific DNA code for a protein.

Genetic association studies

Studies designed to detect differences in the frequencies of DNA polymorphisms in a group of individuals with a particular phenotype contrasted with a group of control subjects from the same population.

Genetic polymorphism

The occurrence of two or more variants (alleles) of DNA sequence in a population. There are many types of sequence variation in the human genome, including single nucleotide polymorphisms (SNPs), microsatellites, deletions, and insertions that have proved valuable for locating genes in human disease using linkage and association strategies. A well-known example of genetic polymorphisms is those giving rise to the proteins of the ABO blood groups.

Genotype

The complete genetic composition of an organism.

Life events

Events usually measured by a trained interviewer using standardized interview schedules to obtain a record of events over a stated time. The inventory is likely to cover common and major events, including financial and marital problems, bereavement, ill health, employment change and infringements of the law. Some investigators separate the effects of different classes of life events, for example, an independent event such as a close friend being involved in an accident is contrasted with the subject him- or herself being in an accident, an event

over which the subject may have some control or which directly threatened him or her.

Phenotype twin studies

The physical expression of the genotype. In genetic research, studies based on the fact that identical (monozygotic, or MZ) twins have exactly the same genes and nonidentical (dizygotic, or DZ) twins share on average 50% of their genes. Both types of twins share similar environments. In characteristics that are genetically determined, MZ twin pairs are more alike (concordant) than DZ pairs, whereas MZ and DZ concordance rates are similar in phenomena due solely to environmental influences.

It has often been taken for granted that anxiety and depression are the natural consequences of stressful events such as sudden bereavement, loss of a job, or marital disharmony and that stresses in childhood such as those related to poor parenting, physical or emotional abuse, or loss of a family member may have an impact on behavior well beyond childhood. However, many early studies of the effects of stressful situations on behavior have not taken into account the effects of genes. It is now abundantly clear that genetic factors play an important and sometimes major role in many human behaviors, personality dimensions, and the development of specific patterns of illness.

How Genes and Stressful Events Can Interact

Kendler and Eaves gave a detailed account of three models to explain how genes and the environment can interact to cause psychiatric illness. These models also help us understand how genetic influences and stressful events interact in everyday life not necessarily associated with psychiatric symptoms. They form a useful basis for discussing a number of recent empirical studies.

The first and simplest model hypothesizes that symptoms of anxiety and depression are the result of the addition of genetic and environmental contributions. This assumes that people, regardless of their genotype, will respond in the same way to an environmental stress, and the probability of being exposed to a stress is independent of genetic background. This model has been the basis of much research in social psychiatry and has, for example, highlighted the

importance of early loss and poor social support as risk factors for the development of depression during adulthood in women. Such a direct causal link between environmental challenges and behavior is illustrated by the normal physiological and behavioral response to a life-threatening situation that is often termed the fight-or-flight response. However, the assumption that environmental stresses and genotype act independently does not explain the empirical observation that some individuals appear to be more sensitive than others to stressful life events.

A second model proposes that genes influence the individual's response to stressful events in the environment. The experience of life events differs widely between individuals and is related to personal characteristics including self-esteem, social support, mood, and personality traits. An example might be that individuals with high scores on neuroticism (a trait that is in part genetically determined) respond to loss or personal threat differently than those with low scores on neuroticism. Animal studies provide an example of how gender differences influence response to stress. Shors and colleagues have reported that the effect of acute stress on memory in rats differs between males and females; the degree of retrograde amnesia or enhanced memory depends on the sex of the animal. This suggests that the genetic differences between the sexes may underlie the expression of different stress response strategies.

Environmental control of the expression of genes is illustrated by animal studies showing that the stress of maternal separation during early development influences the growth of specific brain structures, leading to changes in adult behaviors. Different strains of animals respond differently to early stress, confirming a genetic background to the response. Under this model, however, genotype and environment are not correlated. The model accounts for the influence of genetic factors on the response of an individual to stressful events, but it does not include an effect of genes on the probability that a person will be exposed to stressful environmental situations.

A third, and in many ways the most interesting, model states that a person's genotype alters the probability that he or she will be exposed to a stressful environment. Genes and environment do not act independently, but are correlated. In effect, individuals throughout their lives select the level of environmental stress to which they are exposed. Specific stressful events such as road traffic accidents and injuries at work relate to a number of factors, including personality, drug and alcohol intake, and psychiatric illness. A common but indirect example is a person who is alcoholic and exposed to the consequences of heavy drinking. Since alcoholism is partly a heritable

condition, as shown by family twin and adoption studies, one of the effects of the genes that increase risk of drinking behavior is also to increase exposure of the alcoholic to a range of stressful life events, including marital difficulties, assaults, road traffic accidents, and homelessness. Genes may also influence how a person recalls, perceives, and reports on their experiences of stressful life events.

Measuring Life Events

Over the past 30 years the concept of life events has been developed and refined as a means to study the effects of stressful conditions in the environment on human behavior and psychopathology. Scales such as the Social Readjustment Rating Scale of Holmes and Rahe were developed to be used as a measure of an individual's exposure to environmental stress and have become well-researched tools in social psychiatry. However, the reporting of life events may be influenced indirectly by genetic factors. One of the first studies to address the issue of how life event reporting is governed by social and other factors was carried out in New Zealand by Fergusson and Horwood, who obtained information on life events exposure including financial problems, marital problems, bereavement, ill health, and employment changes over a 6-year period for over 1000 women. The results made it clear that reporting stressful events was not random, and two major determinants of vulnerability to reporting life events were the level of social disadvantage of the woman and her level of trait neuroticism derived from the Eysenk Personality Inventory. Women of socially disadvantaged backgrounds and women with high neuroticism scores consistently reported high exposure to life events over the 6-year period.

Twin Studies of Exposure to Stress

Twin studies that include the comparison of monozygotic (identical) and dizygotic (nonidentical) twin pairs provide a powerful means to quantify the relative contributions to human behaviors of genetic and environmental factors. Rigorous statistical analysis including correlations between twin pairs permits calculation of variance due to genetic factors and shared and individual environments. If a twin experiences a life event that is entirely random and not influenced by his or her personal characteristics, we would not expect the co-twin to show increased likelihood of experiencing a similar event. The co-twin would have the same risk as the general population. If shared family environment was responsible for the life event, both MZ and DZ twins would share an

equally increased exposure. If genetic factors contribute to the event, MZ twins will show greater concordance than DZ twins for that variable because they have more genes in common.

Kendler, in a study of more than 2000 twin pairs selected from the population in Virginia, found clear evidence that reported life events were influenced by both genetic and environmental factors. There was a significant familial resemblance for reported total life events: the correlations for MZ twins (0.43) and DZ twins (0.31) both differed significantly from zero ($p < 0.001$), and the correlation for monozygotic twins consistently exceeded that for dizygotic twins. These results support the view that personality characteristics increase the probability of experiencing stressful life events. The genetic effect was observed only when life events were divided into those that affected the individual directly (personal events), for example, if the individual was in a car accident, as opposed to events involving someone else (network events), for example, if a close relative was in a car accident. Personal events included marital difficulties, being robbed or assaulted, interpersonal difficulties, financial problems, illness or injury, and legal problems, and these were all significantly influenced by genetic factors that explained nearly 20% of the variance. Shared environment had little effect on personal events. In contrast, network events affecting other people were not influenced by genetic factors, and the similarities between twins were entirely attributable to shared family environment. It is understandable that personal events should be under some degree of genetic control, since these events are dependent on the person's behavior whereas network events are not.

This twin study confirmed that the occurrence of stressful life events is more than just bad luck. A combination of familial and genetic influences may predispose the individual to create for themselves a high-risk environment leading to a complex relationship between life events and stress-related disorders. In a further analysis of the female twins from the Virginia Twin Registry, Kendler and Karkowski-Shuman demonstrated that the genetic liability for depression in these twins was associated with an increased risk for stressful life events that included assault, marital problems, job loss, serious illness, financial problems, and social difficulties with relatives and friends. In the same twin sample, the genetic liability to alcoholism was related to the risk of being robbed and having trouble with the police. One of the ways that genes contribute to psychiatric illness is probably by causing individuals to select themselves into high-risk environments. Silberg, in a study of juveniles from the Virginia Twin Registry, proposed a model whereby depression in girls is partly influenced

by genes that mediate adverse life events, and the influence of genes on life events is not stable but increases during adolescence.

Lyons specifically examined how genes influenced exposure to combat trauma in a study of more than 4000 male twin pairs who had served in the Vietnam War. A range of data was collected, including volunteering for service in Vietnam, actual service, a composite index of combat experiences, and the award of combat decorations. Correlations within twin pairs for actually serving in Vietnam were 0.41 (MZ) and 0.24 (DZ), and those for combat experiences were 0.53 (MZ) and 0.3 (DZ). These figures generated an estimate of heritability of 35 to 47%. The family environment had no significant effect on any of the variables, and the results are unlikely to be due to biases from self report because being awarded a combat medal gave similar correlations. The differences between MZ and DZ twin pairs show that exposure to combat is partly heritable and is not influenced by the socioeconomic status of the family of origin. A number of factors could influence combat experience, including the personality trait of novelty seeking, which is known to be genetically determined. Individuals scoring high on novelty seeking will be more likely to volunteer for active service. Similarly, genetic traits that increase the likelihood of a person suffering physical and psychiatric illnesses will act to decrease the likelihood that the person will seek out and experience exposure to trauma in combat.

A twin study by Stein extended these observations to noncombat situations in a study of 400 Canadian civilian twin pairs rated for exposure to trauma and symptoms of posttraumatic stress disorder (PTSD). Seventy-five percent of these twins reported experience of trauma that could be divided into assaultive (robbery or sexual assault) and nonassaultive (road traffic accident or natural disaster). Analysis of heritabilities showed that genetic effects contributed to risk of exposure to assaultive but not nonassaultive trauma, and there was a correlation between genetic effects and PTSD symptoms. It was concluded that many of the same genes that influence exposure to assaultive trauma appear to influence susceptibility to PTSD symptoms in their wake.

Studies of twins have provided important evidence that genetic predisposition has an important role in stress-related activity and the experience of stressful life events ranging from engagement in wartime combat to exposure to assault in civilian life. It is also clear that genetic factors influence how people respond to stress, explaining why some people and not others develop symptoms of PTSD. How these genetic influences are mediated is not known, but a variety of mechanisms have been proposed.

Molecular Genetic Approaches

We can now be fairly sure that a person's complement of genes strongly influences personality traits, but it is highly unlikely that in due course a gene for neuroticism or any other personality dimension will be uncovered. It is more probable that these traits are determined by a number of genes, and the inheritance of different variants of these genes will lead to the particular traits in a manner that has long been familiar to animal breeders.

Complex phenotypes including human personality characteristics are often termed quantitative traits because a number of different genes are thought to act additively in a quantitative manner to produce the phenotype. The genes contributing to the additive effect are termed quantitative trait loci (QTL). The terms polygenic (caused by many additive or interacting genes) and multifactorial (caused by many genes interacting with environmental factors) have also been used to describe the same situation in which a complex phenotype is under a variety of genetic influences. The completion of the sequencing of the human genome, followed by the Hapmap project, which catalogued hundreds of thousands of normal DNA sequence variants (polymorphisms) present at high-density across the genome, have given researchers unrivalled tools for detecting genes contributing to inherited human diseases and complex behavioral traits. Linkage studies use many markers on each of the 23 pairs of chromosomes to identify the small DNA region that is inherited along with a particular disease or trait within a particular family. Another approach for identifying genes contributing to monogenic disease or complex disorders is to study very large cohorts of subjects rated for a particular quantitative trait and compare the frequency of selected DNA polymorphisms between cases and a matched sample of controls recruited from the same population. Association studies are used to study candidate genes or small selected regions of a chromosome previously identified by family linkage analysis. Candidate genes coding for proteins in neurotransmitter pathways, including the serotonin (5-HT) and dopamine systems, have been the focus of particular attention because these neurotransmitters are known from animal and clinical studies to play an important role in regulating mood and a variety of behaviors relevant to traits of impulsiveness, sensation seeking, and addictive behavior. The neurotransmitter 5-HT is an important regulator of early brain development, and 5-HT neurons play known roles in integrating emotion, cognition, and motor function. Genes related to 5-HT are good candidates for a role in human personality, and the 5-HT transporter gene

apparently influences a constellation of traits related to anxiety and depression. Individuals who carry a common small deletion in the promoter region of the 5-HT transporter gene are more susceptible to depression. A possible role for the transporter gene as a mediator of the effects of environmental stress on moods was described by Caspi in a study of a New Zealand birth cohort of individuals. At the age of 26, these individuals were assessed for symptoms of depression and anxiety, and self-reported life events occurring in the previous 5 years were recorded. To address the question of why stressful experience leads to depression in some people and not in others, the 5-HT transporter gene was studied and a crucial difference was observed between individuals who became depressed after experiencing stress and those who were tolerant of stress. Those who became depressed were more likely than nondepressed individuals to carry a small deletion on the promoter region of the gene. This raises the possibility that different variants of the 5-HT promoter gene could moderate how a person is going to react to adverse life experiences.

The neurotransmitter dopamine, like 5-HT, is distributed widely in the nervous system and has a range of functions, including the modulation of mood. It is of considerable interest that a receptor in the dopamine family (DRD4) may influence novelty-seeking behavior. In a study described by Noble, a person who inherits one variety of the DRD4 receptor appears to be more likely to rate highly when assessed for novelty seeking. The same trait was also more common in boys with one particular set of variants in the DRD2 gene. However, the combined DRD4 and DRD2 polymorphisms contributed more markedly to novelty-seeking behavior than when these two gene variants were individually considered. Substantially more needs to be done to unravel the complex relations between stress and symptoms in populations, and it is likely that many more candidate genes will be examined by these methods in large populations to try to detect gene-environment interactions.

Neurotransmitter function is just one of many possible areas of gene-environment interaction providing a link between chronic stress and ill health. An entirely different approach was reported by Epel and colleagues, who investigated the effects on cellular aging of chronic psychological stress experienced by a group of mothers looking after a chronically ill child. They found a significant association between perceived stress and shorter telomere length in peripheral blood mononuclear cells. Telomeres are regions at the ends of each chromosome. It has been noted that telomere length becomes progressively shorter in cells as they age. In this study, the women who reported the highest levels of emotional stress had, on average,

shorter chromosome telomeres than the women who looked after children without disability. Thus, reduced telomere length due to increased oxidative stress in the cell, a determinant of longevity of cells, was associated with perceived psychological stress. It was striking that telomere shortening in women presumed to be under the most stress was shorter on average by an amount equivalent to 10 years of aging compared to low-stress women.

Another area of current interest is how genetic factors during prenatal development and childhood may exert an influence on the way the adult responds to stress several decades later. Welberg and Seckl have extensively reviewed the role of steroids and the hypothalamic-pituitary-adrenocortical (HPA) axis as a system involved in prenatal programming in the brain. In animal studies, prenatal stress leads to long-lasting effects on the HPA axis function in adult offspring, in general programming a persistently hyperactive system and producing clear alterations in the animals' behavior and response to stressful situations. Adult rats exposed to prenatal stress show an increase in behaviors reminiscent of human anxiety. Extrapolation from animal studies to human situations requires extreme caution. However, in a number of clinical studies poor maternal nutritional status in pregnancy and low birth weight were correlated with increased blood pressure, obesity, and glucose intolerance later in life. A possible link between such early life stress and altered behavior or psychopathology in the offspring once they reach adulthood remains an interesting conjecture, and steroids in the HPA axis are the focus of considerable research as possible mediators of such a link.

Overview of Genetic Testing

Stress and Uptake of Genetic Testing

Emotional Impact of Genetic Testing

Cognitive Appraisal of Genetic Testing

Glossary

<i>Autosomal recessive condition</i>	A genetic condition in which both copies of a gene need to be faulty in order for the specific condition to develop.
<i>Carrier testing</i>	A test to identify whether an individual has one copy of the faulty genes that contribute to an autosomal recessive condition.
<i>Human genome project</i>	An international collaboration to map the entire human genome.
<i>Mutation</i>	An inherited change in a sequence of DNA.
<i>Predictive genetic testing</i>	A test to identify whether an asymptomatic individual has a genetic mutation that predisposes him or her to developing a specific disease.

Overview of Genetic Testing

The knowledge generated by the Human Genome Project has already started to revolutionize our understanding of health and illness. It is now possible to identify people who have a genetic predisposition to an increasing number and variety of diseases. This knowledge offers great potential for disease prevention, developing more effective treatments, and, indeed, the hope of treating diseases that are currently incurable. This new understanding of the human genome also brings with it a whole host of ethical, social, and psychological dilemmas. Although genetic testing for certain conditions means that those at risk can reduce their chances of developing the disease, for other conditions genetic testing means that some people have to live with the knowledge that they are almost certain to develop an incurable disease. Genetic testing has implications for decisions about whether to have children and who to have them with, what to do if a fetus is known to have a genetic disease, and whether individuals will be discriminated against when seeking employment or insurance.

In this article, we focus on the role of stress in predictive genetic testing. This is because most of the well-conducted psychological evaluations conducted to date that assess stress using validated measures concerned predictive genetic testing. Also, in other forms of genetic testing, such as carrier testing, the psychological issues primarily concern decisions about pregnancy and childbirth. Carrier testing is concerned with identifying people who have a copy of a deleterious mutation for an autosomal recessive condition. These people do not develop the disease in question, but if they have children with someone who is also a carrier of the mutation, each child has a 25% chance of having the condition. Examples of these conditions are Tay-Sachs disease, sickle cell disease, and cystic fibrosis. Predictive genetic testing is concerned with identifying people who are at high risk of developing the disease themselves. All of the predictive genetic tests currently available raise different medical, psychological, and ethical issues.

One of the first genetic tests developed was for Huntington disease, an incurable neurodegenerative condition that typically develops in middle age or later life. People who carry the mutation definitely develop Huntington disease at some point, and those who do not carry the mutation definitely do not develop the disease. There is understandable concern that offering at-risk families genetic testing will constitute an enormous psychological burden for those who test positive. There are a number of exemplary longitudinal studies conducted worldwide to evaluate the consequences of genetic testing for these families. There are also an increasing number of psychological evaluations of genetic testing for a predisposition to cancer, particularly breast and ovarian cancer but also forms of colon cancer. In these cases, the psychological issues include the stress that may be associated with being found to be a carrier of a predisposing mutation and behavioral responses to genetic risk information. These behaviors include whether people adhere to recommendations about surveillance to detect possible cancers and also decisions about whether to have surgery to remove tissues likely to be affected prior to the development of any cancer (called prophylactic surgery). In the case of an inherited predisposition to cancer, being a carrier of a mutation increases the cancer risk considerably, typically making the likeliness of developing cancer 60–80%, but it does not make cancer inevitable. In addition, those found not to carry the genetic

mutation still have at least the same risk as the general population of developing cancer, which means it is important that these people do not believe they are not at risk. For other diseases, genetic testing is still in its infancy. For example, it is possible to offer predictive genetic testing for the predisposition to coronary heart disease and Alzheimer's disease. In the case of coronary heart disease, predictive genetic testing can be offered for familial hypercholesterolemia, an inherited predisposition to raised cholesterol levels. Because the treatment for this condition, in the form of cholesterol-lowering statin medication, is very effective, the psychological issues raised pertain particularly to preventative behavior, that is, whether those identified adhere to medication regimens and engage in other risk-reducing behaviors such as eating a low-fat diet and not smoking. Like Huntington disease, Alzheimer's disease is not curable at present. However, genetic testing for Alzheimer's indicates whether an individual has an increased risk for the disease rather than providing the information that an individual definitely will or will not go on to develop it. In this case, it is necessary for those undergoing testing to understand quite complicated probabilities.

Genetic testing programs differ in how they are organized. In some cases, everyone within a particular population may be offered genetic testing. Such population-based screening programs are most common for detecting carriers of recessive genes and for the prenatal and neonatal screening of infants. More common among predictive genetic testing programs is some form of cascade screening. These programs start with an individual who either has the disease or is at known risk (called the proband) and, if a deleterious mutation is identified in this individual, genetic testing is then offered to other biological relatives.

All these factors have an impact on the emotional state, risk perceptions, and expectations of those offered genetic testing and receiving the results of genetic tests. An interactional model of stress is widely accepted within the stress community, whereby stress is conceptualized as a process involving an interaction of individuals and their environment. One such example is the transactional model of stress and coping proposed by Lazarus and Folkman in the 1980s. Using this framework, we address three main questions with respect to genetic testing: does stress influence the decision to have a genetic test, is receiving the results of genetic testing stressful, and does genetic testing influence secondary appraisal processes and coping strategies? Each of these issues is now considered in turn.

Stress and Uptake of Genetic Testing

It is widely recognized that feelings of stress about health lead people to be more likely to engage in risk-reducing behaviors such as stopping smoking, taking exercise, and adopting a healthy diet. The picture with regard to disease-detecting behaviors, of which having a genetic test is one example, is less clear cut. Disease-detecting behaviors are actions that can inform the individual whether they have or are likely to develop a particular disease but that, in themselves, do not change the disease or risk status of the individual. Similar to models of stress and behavioral performance in nonhealth domains, it has been proposed that a certain amount of perceived stress motivates the performance of disease-detection behaviors. However, high levels of perceived stress are thought to lead to a greater likelihood of fear-control strategies and the subsequent avoidance of the behavior.

Only a proportion of those offered genetic testing will decide to have the test. There are a wide variety of factors influencing this decision, including the disease being tested for and whether treatment is available, sociodemographic factors, and the expectations and motivations of the individual. Whether greater perceived stress facilitates or inhibits the uptake of the offer of genetic testing has not been widely investigated. What is known is that people who believe they can cope with the results of genetic testing are the ones who have a greater interest in and uptake of genetic testing. In addition, people's perceiving themselves as being at greater risk for having the gene and developing the disease is typically associated with a greater uptake of genetic testing. In one of the early reports of genetic testing for Huntington disease, the Canadian Collaborative Study of Predictive Testing group found that participants who declined genetic testing (along with those who received uninformative test results) were the most distressed over a period of 12 months. In 1997 Caryn Lerman and colleagues explicitly tested the influence of distress on requesting the results of genetic testing for hereditary breast and ovarian cancer susceptibility. After controlling for sociodemographic factors and objective risk, those with higher levels of cancer-specific distress were nearly three times more likely to request the results of genetic testing. No evidence of a curvilinear (inverted-U) relationship between distress and genetic testing was found, although this may be because, on the whole, participants did not have high levels of distress. Although there are inherent difficulties in investigating whether stress predicts the uptake of genetic testing given that people who decline the offer of genetic testing are less likely to want to take

part in psychological evaluations, there is clearly a need to attempt to understand this relationship. As genetic testing becomes more ubiquitous, there is a need to find out whether those who are offered genetic testing and decline it constitute a particularly vulnerable group.

Emotional Impact of Genetic Testing

Given the justifiable concern that finding out one has a high risk of developing a serious genetic disease may prove to be a huge burden, it is unsurprising that the most widely investigated issue over the past 20 or so years has been the emotional impact of receiving genetic test results. The original studies continue to report the long-term emotional effects of testing, and more studies are needed as new genetic testing procedures for various diseases are implemented. As already discussed, having an uninformative genetic test result for Huntington disease (along with declining the genetic testing) was found to be more distressing than receiving a positive result. An uninformative genetic test result is one in which it is not possible to definitively state whether or not the individual is a carrier of a deleterious mutation. In this study, the higher distress of those receiving uninformative results was quite possibly due to the motivation for testing. Many people who seek predictive genetic testing do so hoping to resolve the uncertainty they have been living with, and uninformative results fail to help them achieve this goal. Most studies, however, report the impact of positive and negative genetic test results and these are considered next.

Negative Genetic Test Results

As might be expected, across different genetic tests, a consistent finding is that immediately after individuals learn they do not have the predisposing gene they experience psychological relief. Thus levels of anxiety, depression, distress, and illness-specific measures of distress typically drop to significantly lower levels than they were at the time when baseline assessments were made. Some studies find that these lower levels of psychological stress are maintained over the coming months and years, whereas other studies find that the level of stress slowly rises back to the baseline level. This latter finding may well be explained by the fact that the threat of disease is but one of the problems that individuals face. Despite the relief invoked by not being a carrier of the disease-causing gene, other problems remain unresolved and quickly start to impinge on the individuals' emotional state. In addition, these people come from families affected by serious diseases and still need to cope with this

situation and, possibly, the feelings of guilt that others are affected when they are not.

A consistent finding across studies is that distress prior to testing is the biggest predictor of distress after testing, regardless of the test result. A positive effect on the mean stress levels in individuals who receive a negative test result can hide the fact that some individuals have problems coping with testing negative for the gene. These people may have lived their lives and made important decisions (such as not having children) on the basis of their expectation of developing the disease in the future. Almqvist and colleagues recently reported that one person who tested negative for the gene for Huntington disease attempted suicide on the day he received the test result. Therefore, it is important that it not be assumed that all patients who receive negative genetic test results do not require additional support and counseling.

Positive Genetic Test Results

Some studies found that, immediately after receiving positive genetic results, people's levels of distress are no different than their baseline levels. Other studies found increased levels of distress in this group. An unexpected and important finding is that any increased distress is usually transitory. As early as 1 month and for at least 1 year after being given this bad news, the levels of distress are consistently no different to those reported for the baseline levels. In some studies, the levels of distress up to 1 year later are no different than the levels reported by those receiving negative test results. As with the finding for negative test results, a concentration on the mean scores can hide the fact that some individuals do experience great and long-term difficulties coming to terms with the information that they are at high risk of developing a serious disease. There is a need to ensure that these individuals, in particular, receive appropriate support in the months and years following the receipt of genetic test results. Because distress prior to testing predicts distress following testing, the process of identifying potentially vulnerable individuals can be put in place as soon as they come forward for testing.

Huntington disease was the first disease for which a predictive genetic test was developed, and these studies were also the first to report the results of long-term psychological evaluations. These are crucial because they show whether those who receive positive genetic tests start to experience greater distress when they approach the time when they can expect to develop symptoms. In 2003, Almqvist and colleagues reported that for those who carry the gene for Huntington disease the levels of distress,

which were reduced soon after testing and up to 2 years later, had increased at the 5-year assessment. However, this increase was no higher than the baseline levels of distress. Although some participants did report distress levels in the clinical range, the mean scores were below the clinical cut-off at all the times measured. Therefore, there are reasons to be optimistic that, for the majority of people, genetic testing does not result in psychological harm.

Many authors have noted that there are a variety of explanations to account for the finding that positive test results do not, on the whole, lead to long-term emotional difficulties. Most of the people undergoing predictive genetic testing have lived most of their lives with the knowledge that their family members are affected by this disease and that they are at risk. Thus, many enter genetic testing programs with the hope of resolving uncertainty about their own risk status and that of their relatives. In many contexts, living with uncertainty can be more stressful than certainty. In addition, only a proportion of those who are at risk decide to have genetic tests, and, as stated previously, these are typically those who feel they can cope with the results. Finally, many of the genetic testing programs evaluated to date have at their core the provision of excellent information and counseling, and this will make no small contribution to the psychological well-being of recipients of genetic testing. There is a need to ensure that, when genetic testing is expanded to other clinical environments and other diseases for which people may have less awareness of their own risk, it is still accompanied by the provision of high-quality information and support.

Cognitive Appraisal of Genetic Testing

There are rapid developments in the understanding of the genetic basis of multifactorial diseases such as cancer, cardiovascular disease, and diabetes, in which both genetic and behavioral factors can contribute to developing the disease. In this context, whether genetic testing influences the cognitive appraisal of the disease becomes a key issue. If having a genetic test leads people to appraise the disease differently, this may have implications for whether they will engage in behaviors that can reduce their risk.

In the general public, studies suggest that there is a common perception that the genetic risk of disease is less controllable than other risk factors. From a stress and coping perspective, the appraisal of a health threat as uncontrollable could initiate different coping procedures than its appraisal as controllable. Specifically, genetic risk information could invoke fatalism and could demotivate the individual from engaging in risk-reducing behaviors. This hypothesis

was tested – and was not supported – in a UK trial of genetic and nongenetic diagnoses of familial hypercholesterolemia. In this study, genetic testing appeared to influence the cognitive appraisal of the disease by reinforcing a biological model of the disease, such that the more genes were endorsed as contributing to coronary heart disease, the more medication was endorsed as an effective means of reducing risk. Thus, there is some preliminary evidence that genetic risks are indeed appraised differently and may lead to greater engagement in biological rather than behavioral ways of reducing risk. As with the majority of the studies conducted to date, this research was conducted with participants already highly aware of their increased risk of disease.

Some studies have found that genetic test results do have an impact on behavior, such as an increased adherence to surveillance behaviors in those with an inherited predisposition to cancer. Indeed, some people who are found not to have a genetic predisposition to cancer find it difficult to accept that their risk is at the same level as the general population and still desire regular screening to detect cancer. To date there is little evidence to suggest that such populations feel falsely reassured that a negative genetic test means they have no risk of developing the disease. Some people who do have an inherited predisposition to cancer opt to have prophylactic surgery (e.g., a mastectomy before any cancer has developed). Although this is clearly a difficult decision, the option to undergo surgery is an understandable coping strategy for those who have seen family members affected by cancer. Other studies, however, have not found any behavioral effects of genetic testing.

Given the equivocal findings across the few studies to date that have investigated behavioral outcomes, there is a need for improving our understanding of the mechanisms that may explain these differences. A number of authors are beginning to conceptualize the impact of genetic testing from a stress and coping and from a self-regulatory perspective. These conceptualizations should pave the way for developing an evidence base of the mechanisms by which cognitive and emotional appraisal and self-regulatory processes impact on behavior following genetic testing. This developing evidence base will lead to a greater certainty about how best to implement genetic testing for multifactorial diseases. In particular, as genetic testing for common diseases such as cancer and coronary heart disease becomes more widespread, there is a need to investigate the impact of genetic testing on cognitive appraisal and behavior in populations that have less prior awareness of their risk. These populations may have very different emotional responses and cognitive appraisals of their risk status than the

highly aware populations studied so far. Based on the evidence to date, however, there is cause for cautious optimism that if attention is paid to providing high-quality information and support to at-risk families the potential medical benefits of genetic testing can be realized without causing emotional or behavioral harm.

Glossary

Corticosteroid-binding globulin (CBG) A glycoprotein specifically carrying glucocorticoid hormone in blood plasma.

Genotype The specific genetic makeup (the specific genome) of an individual. It codes for the phenotype of that individual.

Heritability The proportion of the observed variation in a particular phenotype and, in

Hypothalamic-pituitary-adrenal (HPA) axis
Phenotype

a particular study, that can be attributed to the contribution of genotype (inheritance).

The neuroendocrine system responsible for glucocorticoid hormone secretion.

A specific manifestation of a trait that varies between individuals. The phenotype is determined to some extent by genotype, or by the identity of the alleles that an individual carries at one or more positions on the chromosomes. Quantitative phenotypes are determined by multiple genes and are influenced by environmental factors.

Quantitative trait locus (QTL)

A polymorphic site on a chromosome containing alleles that differentially influence the expression of a quantitative trait.

Single nucleotide polymorphisms (SNPs)

Stable mutations consisting of a change at a single base in a DNA molecule. They are the most common type of genetic variation.

Evidence for Genetic Variability

A wide range of variability has been observed in hypothalamic-pituitary-adrenal (HPA) axis function, both basal and in response to stress. The contribution of genetic factors is shown by the differences among genetically defined stocks. Most available data have been obtained from pigs. Wild boars have the highest levels of cortisol, followed by Chinese breeds, including the most-studied Meishan. The highly selected lean breeds Large White and Landrace have the lowest levels, and Piétrain and Duroc pigs show intermediate levels. Few data are available in other species.

If a trait is influenced by genetic factors, it should be possible to increase or decrease the value of this trait by genetic selection. Indeed, divergent lines have been obtained by genetic selection in poultry (response to adrenocorticotropin [ACTH] or social stress), Japanese quail (response to immobilization), turkey (cold stress), and trout (confinement stress).

Sources of Genetic Variability

This article will not deal with major gene effects on HPA axis activity as seen in endocrine diseases induced by corticosteroid receptor or enzymatic defects. Traits such as circulating cortisol levels are normally distributed in genetically heterogeneous populations, suggesting that several genes may influence the phenotype, each gene with a small effect, and with complex gene $\times$ gene and gene $\times$ environment interactions. Several sources of genetic variability have been identified in farm animals.

Adrenal Sensitivity to ACTH

In the 1980s, D. P. Hennessy (Victoria, Australia) demonstrated in pigs that the increase of plasma cortisol after ACTH injection was variable among individuals but stable across time for a given animal. Similar differences in cortisol secretion were shown in response to corticotropin-releasing hormone (CRH), physical exercise, or insulin-induced hypoglycemia, although the release of ACTH was not different among individuals. Furthermore, the metabolic clearance of cortisol bears no relationship with the response to ACTH. Altogether, these data demonstrate that the key index of individual differences in HPA axis activity is the adrenal sensitivity to ACTH that was shown to be heritable in pigs. Several experimental results confirm genetic influences on the sensitivity of adrenal glands to ACTH. For instance, Meishan pigs (high cortisol levels) have a higher response to ACTH than Large Whites (low cortisol). In poultry, divergent lines could be selected on this trait. In quails,

selection for high corticosterone to immobilization increased the steroidogenic response of adrenocortical cells to ACTH, and in turkeys, selection for a high corticosterone response to cold stress also increased the sensitivity of the adrenal gland to ACTH. In trout, the divergent cortisol response to confinement stress mostly results from the selection of animals with divergent interrenal gland response to ACTH, together with a large difference in the expression level of genes involved in corticosteroid hormone synthesis. Taken together, these data show that the adrenal sensitivity to ACTH is an important mechanism by which genetic factors influence HPA axis response to stress.

Hormone Bioavailability

Quantitative trait locus (QTL) analysis is a strategy to search for gene polymorphisms influencing a quantitative trait. It is based on the linkage between phenotypic value and genetic polymorphisms in a segregating population, usually an F2 intercross or a backcross. A QTL analysis run on an F2 intercross between the Large White and Meishan breeds revealed the large influence of a locus located at the end of the q arm of chromosome 7 on basal and post-stress (novel environment exposure) levels of cortisol, explaining, respectively, 7.7% and 20.7% of the phenotypic variance, with the Meishan alleles increasing cortisol levels. Other loci on chromosome 1 and 17 were shown to influence poststress ACTH levels. The comparison of genetic maps from different species shows that the end of the long arm of chromosome 7 is homologous to the telomeric end of the long arm of human chromosome 14. In this region corticosteroid-binding globulin (CBG), a glycoprotein specifically carrying cortisol in blood plasma, has been mapped. CBG is an important factor influencing bioavailability of the hormone, as it has been shown in humans that differences in CBG levels are a major determinant of differences in plasma cortisol levels. Therefore, the *Cbg* gene is an interesting positional and functional candidate gene to explain QTL influences on plasma cortisol levels. Indeed, comparison of gene sequences in Large White and Meishan pigs revealed several polymorphisms influencing CBG levels and function.

Corticosteroid Hormone Receptors

Two receptors (mineralocorticoid receptor [MR] and glucocorticoid receptor [GR]) mediate the biological effects of corticosteroid hormones. They act as transcription factors to increase or decrease the expression of target genes. The efficiency of corticosteroid hormone receptors is a major site of genetic variation, but few data are available in farm animals.

Functional Consequences of Genetic Variability

Physiopathological consequences of genetic variations in HPA axis activity reflect the wide range of corticosteroid hormone functions. Most data are related to growth and carcass composition. Indeed, glucocorticoid hormones influence feeding behavior; they also exert catabolic effects in peripheral tissues and anabolic effects in the liver so that they reduce growth rate and promote the accumulation of fat at the expense of proteins. In pigs, breeds with a higher body fat content such as Duroc and Meishan also produce more cortisol than lean breeds such as Large White and Landrace. In a segregating population (F2) of Large White $\times$ Duroc pigs, the fat content of the carcass was positively correlated with urinary levels of cortisol measured in the bladder after slaughter. In other studies in pigs, the magnitude of the adrenal response to ACTH – the main mechanism of genetic variability in HPA axis activity – was shown to be negatively correlated with body weight and growth rate. In sheep and turkeys, selection for leanness is accompanied by a reduction of HPA axis reactivity. Conversely, selection for a reduced adrenal response to cold stress in turkeys also increased body weight and egg production in turkeys, and growth rate was also inversely related to cortisol levels in divergently selected lines of rainbow trout.

Glucocorticoid hormones are also potent modulators of the immune system, and data obtained in chickens illustrate the consequence of genetic variation in HPA axis activity/reactivity on resistance to parasites or infectious diseases.

Perspectives

Current research in molecular genetics aims at the identification of gene polymorphisms responsible for individual phenotypic variation. For instance, there are documented mutations in the *Cbg* gene modifying its functional properties and associated with variable carcass fat content and meat quality of pigs. A single nucleotide polymorphism in the *CRH* gene was found to influence rib-eye area and carcass weight in beef cattle. In the future, it should be possible to optimize the functioning of the HPA axis by genetic selection based on molecular polymorphisms. When considering growth rate and carcass fat content, a low level of cortisol production should be favorable in the context of modern breeding for

meat production. However, the picture is much less clear when considering the influence of HPA axis on other phenotypes. For instance, a lower cortisol response to social stress in poultry can either increase or decrease resistance depending on the infectious agent, and recently it was shown that plasma cortisol levels measured at birth are the best predictor of the genetic merit for piglet survival, with highest levels increasing survival. Further research will be necessary to better define the optimal activity of the HPA axis and to refine the molecular tools for farm animal selection.

These compounds play an essential role in the control of gastrointestinal circulation and gastrointestinal mucosal defense. A group of arachidonic acid metabolites which include mainly prostaglandins and thromboxanes.

One of the important growth factors, responsible for angiogenesis and acceleration of ulcer healing and process of gastrointestinal mucosal repair.

Glossary

D cells Endocrine cells belonging to the amine precursor uptake and decarboxylation (APUD) system known to release the hormone, somatostatin.

Endocrine cells (EC) Release the hormone motilin and the neurotransmitter serotonin.

Enterochromatoffin-like cells (ECL) Known to release histamine, a potent stimulant of gastric acid secretion in the stomach. They are the predominant endocrine cell-type of the oxyntic (acid-producing) mucosa of the stomach. Histamine acts as the positive paracrine stimulator of the release of hydrochloric acid from the parietal cell.

Gastric blood flow (GBF) Defined as the flow of the blood through submucosal vessels in the gastric mucosa.

Gr cells Ghrelin-producing cells identified in the gastric mucosa.

N^G-nitro-L-arginine (L-NAME) A nonselective inhibitor of the enzyme nitric oxide synthase. It has been used experimentally to induce hypertension.

Neuropeptides Small proteins (peptides) comprised of a chain of amino acids that are synthesized in, and secreted by, nerves and serve as neurotransmitters (when released at

Pathogenesis of Stress-Induced Gastric Ulcerations

Stress ulcerations are defined as acute gastric mucosal lesions occurring as complications in severely ill patients after burns, sepsis, major surgery, or trauma to the central nervous system. Critically ill patients are at increased risk of developing stress-related gastric mucosal lesions and gastrointestinal bleedings. Stress can induce acute gastric mucosal lesions by a complex of psychological factors, psychosis, or brain trauma, influencing individual vulnerability and specific brain pathways regulating autonomic functions. These stress-induced gastric microbleeding erosions are accompanied by a marked decrease in the gastric blood flow (GBF), a substantial decrease in the

gastric mucosal prostaglandin (PG) content and nitric oxide (NO) release, inhibition of gastric mucus and bicarbonate secretion, and the increased formation of free oxygen radicals in the gastric mucosa leading to gastric ischemia and inflammation. Among various stress models used in animals, the most reproducible results can be obtained by water immersion and restraint stress (WRS), which appear to act synergistically in the production of gastric ulcerations. Numerous studies have demonstrated the usefulness of cold-restraint stress and proved it to be a clinically relevant experimental model for studying of pathomechanism of acute gastric damage and protection. It has been shown that gastric acid plays an important role in the development of stress-induced gastric ulcer and is the most common endogenous factor responsible for the destruction of epithelial cells. Gastric mucosal lesions induced by different time-dependent exposures to WRS trigger time-course dependent changes of the ultrastructure of gastric parietal cells secreting gastric acid. Many physiological agents such as PG, NO donors, calcitonin gene-releasing factor (CGRP), and gastrointestinal hormones such as cholecystokinin (CCK) and leptin have been reported to attenuate the gastric erosions induced by stress of different origin and durations. The mechanism of the recovery of gastric mucosa from stress injury is not fully understood and the underlying healing of stress-induced gastric lesions appears to be multifactorial. It has been proposed that mucosal integrity and mucosal repair after stress damage, involve the enhancement of GBF and increased cell proliferation mediated by expression and subsequent release of growth factors such as epidermal growth factor (EGF) and transforming growth factor (TGF)- α .

Discovery, Receptors, and Physiological Functions of Ghrelin

Ghrelin is a recently described 28-amino acid peptide that has been discovered in rat and human gastrointestinal tracts, particularly in gastric mucosa, as an endogenous ligand for growth hormone (GH) secretagogue receptor (GHSR). Ghrelin stimulates food intake and body weight gain exerting a modulating effect on energy expenditure acting through afferent nerves and directly on hypothalamic feeding centers. This peptide was also shown to enhance the gastric motility and gastric secretion. Recent studies revealed that ghrelin is produced by special neuroendocrine cells located mainly in oxyntic mucosa but not in enterochromatoffin-like cells (ECLs), endocrine cells (ECs) or D cells. Ghrelin has no relevant homology with any known gastrointestinal peptides but

potently stimulates the release of GH and acts as a natural ligand for the GHSR which is the endogenous counter of the family of synthetic, peptidyl and non-peptidyl GH secretagogues. Ghrelin stimulates food intake and body weight gain exerting a modulating effect on energy expenditure. Administration of ghrelin causes weight gain via appetite stimulation and reduced fat oxidation. The release of ghrelin may be influenced by the status of fasting and nutrient feeding because central and peripheral administration to rats results in an increase in their feeding behavior. Previous studies in humans revealed that gastrectomy produced a dramatic fall in the plasma ghrelin levels, whereas fasting and anorexia nervosa were accompanied by elevated plasma ghrelin concentrations supporting the notion that the gastrointestinal tract, primarily the stomach, is a major source of circulating ghrelin, which could be considered as a starvation-related hormone. Interestingly, obestatin, which is encoded by the same gene as ghrelin has recently been reported to counteract physiological effects of ghrelin.

A recent study revealed that endocrine Gr cells of the stomach are a major source of circulating ghrelin acting via activation of two receptor subtypes. Two GHS-R subtypes are generated by alternative splicing of a single gene: the full-length type 1a receptor (GHS-R1a); and a carboxyl-terminally truncated GHS-R type 1b (GHS-R1b). The GHS-R1a is the functionally active, signal-transducing form of the GHS-R, while the GHS-R1b is devoid of high-affinity ligand binding and signal transduction activity. Ghrelin molecules, produced by endocrine cells of gastric glands exist in two major molecular forms, ghrelin and des-*n*-octanoyl ghrelin (des-acyl ghrelin). The acylation by *n*-octanoic acid of the hydroxyl group of their third residue, which is either serine or threonine, is essential for binding of ghrelin to GHS-R1a. The anorexia associated with cancer chemotherapy in rodents is reported to be alleviated by exogenous ghrelin and similar effects have been described in humans. This may be due to a reduction in activity of ghrelin-producing cells, present predominantly in the oxyntic mucosa.

Role of Ghrelin in Maintenance of Gastric Mucosal Integrity

Little is known about the factors that might affect ghrelin release in the stomach and whether this peptide can contribute the mechanism of gastric mucosa integrity. The role of ghrelin in the mechanism of gastric mucosal defense and gastroprotection has been investigated by revealing that peripheral administration of ghrelin reduces the formation of lesions induced by ethanol and cold stress ([Figure 1](#)).

Figure 1 The mean number of water immersion and restraint stress (WRS)-induced gastric lesions, gastric blood flow (GBF), and plasma immunoreactivity of ghrelin in rats treated with vehicle (saline) or with various doses of ghrelin (5–80 µg kg⁻¹ intraperitoneal). Please note a significant and dose-dependent reduction in the number of gastric lesions induced by WRS accompanied by a significant rise in the GBF and plasma ghrelin levels. Means ± standard error of means of 6–8 rats. Asterisk indicates a significant change as compared to the vehicle control values. Reproduced from *Regulatory Peptides* 120, Exogenous and endogenous ghrelin in gastroprotection against stress-induced gastric damage. 39–51, 2004, with permission from Elsevier.

In agreement with the original hypothesis that prostanooids, NO, and sensory neuropeptides cooperate in the mechanism of maintenance of gastric integrity, it was proposed that NO and sensory neuropeptides may mediate these gastroprotective effects because the blockade of NO synthase (NOS) activity with N^G-nitro-L-arginine (L-NAME) and the functional ablation of sensory afferent nerves with capsaicin were both found to attenuate them. It is of interest that centrally applied ghrelin can influence gastric acid secretion, while attenuating lesions caused by stress and this effect is mediated by the vagal innervation and the expression of calcitonin gene related peptide (CGRP) messenger ribonucleic acid (mRNA), an important neuropeptide released from sensory nerve endings. Both these events are considered as important components of the brain-gastrointestinal tract axis involved in the gastroprotective effects of ghrelin especially against stress-induced gastric lesions.

In contrast, the *Helicobacter pylori* (*H. pylori*) infection of the human gastric mucosa which is now considered to play a role as the causal factor in the pathogenesis of gastritis and peptic ulcer was found to attenuate the mucosal expression and release of ghrelin and to reduce appetite. This was confirmed in *H. pylori*-infected gastric mucosa of Mongolian gerbils, which is now widely accepted as an appropriate model to study the mechanism of *H. pylori* infection under experimental conditions. It is of interest, that after successful cure of *H. pylori* in

healthy asymptomatic subjects the plasma ghrelin concentration increased, which in turn led to enhanced appetite and weight gain. This implies that increase in ghrelin in *H. pylori* cured gastric mucosa may contribute to the increasing obesity seen in Western populations, where the prevalence of *H. pylori* is low.

Mechanism of Gastroprotection Induced by Ghrelin

Recently, endogenous PGs have been implicated in the control of food intake and appetite but the possibility that these cytoprotective arachidonic acid metabolites could also play an important role in the gastroprotective effect of ghrelin has not been explored. Moreover, the question remains whether ghrelin contributes to gastroprotection against gastric lesions caused not only by artificial irritants such as ethanol, but also can protect against those caused by vascular disturbances resulting from stress or ischemia-reperfusion (I/R) that lead to severe microbleeding erosions and the fall in the microcirculation (Figure 2). Therefore it was important to confirm whether endogenous PGs as well as the expression of cyclo-oxygenase (COX)-1 and COX-2 are involved in the possible gastroprotective activity of ghrelin against stress-induced gastric erosions.

Our study supports the notion that ghrelin-induced protection and hyperemia involves co-activation of NO and sensory afferents and endogenous PG.

Figure 2 Representative photomicrograph showing gross appearance of gastric mucosa of rat pretreated 30 min before the exposure to 3.5 h of water immersion and restraint stress (WRS) with a, vehicle (1 ml of saline intraperitoneal (IP)) or b, ghrelin ($20 \mu\text{g kg}^{-1}$ IP). Please note that many bleeding erosions are observed macroscopically in vehicle-pretreated gastric mucosa as compared to that treated with ghrelin indicating a protective activity of this hormone against the formation of WRS-induced gastric lesions.

Arachidonic acid metabolites were believed to act as the classic mediators of cytoprotection but recent studies revealed that in contrast to NO, endogenous PG do not appear to contribute to the observed gastroprotection by peptides such as leptin and CCK against ethanol-induced gastric lesions. Questions arose whether the suppression of COX by nonselective COX inhibitor, indometacin, or the highly selective COX-2 inhibitor, rofecoxib, could influence the gastroprotective and hyperemic activity of ghrelin. It has been documented that ghrelin-induced protection and hyperemia is accompanied by the enhancement in the mucosal PGE_2 generation. Both, indometacin and rofecoxib greatly attenuated the protective and hyperemic effects of ghrelin, indicating that endogenous PG possibly derived from COX-1 and COX-2 PG pathway may mediate these beneficial effects of this hormone on the stomach (Figure 3).

Ghrelin applied centrally exhibits comparable gastroprotective activity as when administered peripherally against the mucosal damage induced by corrosive substance such as ethanol and nontopical ulcerogen such as stress. This suggests that exogenous ghrelin could be considered as an important protective factor for the gastric mucosa. This notion is supported by observation that ghrelin attenuated the gastric lesions induced by ethanol in various concentrations and those provoked by stress while producing an increase in gastric mucosal blood flow and the plasma level of this hormone. The results of secretory studies revealed that ghrelin applied by the intracerebroventricular (ICV) and intraperitoneal (IP) routes in doses that were gastroprotective against stress and ethanol injury significantly raised gastric acid secretion suggesting that the protective effect of this peptide occurred despite an increase of the gastric secretory function,

thus representing genuine gastroprotective activity as previously proposed for the phenomenon of cytoprotection. The ghrelin-induced protection after its central administration was accompanied by a significant and dose-dependent rise in the plasma ghrelin concentrations by WRS suggesting that ghrelin-evoked gastric hyperemia could be an important mechanism of the protective effect of this peptide in rat stomachs (Figure 1).

It has been shown that ghrelin, primarily produced in the stomach, but also in the hypothalamus, is an orexigenic peptide and affects both feeding at the levels of hypothalamus (arcuate nuclei) and GH secretion partly due to an activation of gastric vagal afferents transmitting visceral sensory signals to the brain. The observation that ghrelin stimulates gastric acid secretion is in keeping with the original observation that an increase in gastric secretion was achieved after parenteral but not topical administration of ghrelin. The mechanism by which ghrelin increases gastric acid secretion after peripheral as well as central administration could be related to elevation of plasma gastrin concentration, since a considerable increase in this hormone level was notified following ghrelin application. Gastrin could contribute, at least in part, to the secretory as well as protective and hyperemic effects of ghrelin but its effect on histamine release should also be considered. The notion that the protective activity of ghrelin depends, at least in part, on gastrin release is at variance with some studies claiming that ghrelin release does not operate under gastrin; however, these studies failed to directly address the effect of ghrelin on gastrin release. It is not excluded that ghrelin, which is known for the release of GH, acts via GH release to protect gastric mucosa against stress damage as GH was shown to

Figure 3 The mean number of gastric lesions induced by water immersion and restraint stress (WRS) and accompanying changes in gastric blood flow (GBF) in rats treated with vehicle (saline) and ghrelin ($20 \mu\text{g kg}^{-1}$ intraperitoneal (IP)) with or without pretreatment with nonselective COX inhibitor, indometacin (5 mg kg^{-1} IP) or COX-2-selective inhibitor, rofecoxib (10 mg kg^{-1} intragastric). Mean $\pm$ standard error of mean of 6–8 rats. Asterisk indicates a significant decrease as compared to the value obtained in vehicle-control animals. Cross indicates a significant change as compared to the respective value obtained in animals without pretreatment with COX inhibitors. Double cross indicates a significant change as compared to the respective value obtained in ghrelin-treated animals without pretreatment with COX inhibitors. Reproduced from *Regulatory Peptides* 120, Exogenous and endogenous ghrelin in gastroprotection against stress-induced gastric damage. 39–51, 2004, with permission from Elsevier.

enhance the healing of gastric ulcers, while increasing plasma gastrin level.

Neural Aspects of Gastroprotective Activity of Ghrelin

Ghrelin is an orexigenic peptide and affects both feeding at the levels of hypothalamus (arcuate nuclei) to stimulate neuropeptide Y (NPY) and Agouti-related peptide (AgRP)-related neurons and to release GH partly due to an activation of gastric vagal afferents transmitting visceral sensory signals to the brain. An experimental study in a stress model of gastric injury revealed that ghrelin mRNA was upregulated in the gastric mucosa exposed to WRS. This was followed by an increase in the plasma ghrelin level indicating that endogenous ghrelin might act as local integrity peptide to limit the extent of gastric damage provoked by WRS. This is similar to leptin, another gastric hormone involved in the control of food intake though acting in opposite direction than ghrelin. As expected, ghrelin-induced protection after its central administration was accompanied by a significant and dose-dependent rise in the plasma ghrelin concentrations and marked attenuation of the fall in the GBF caused by WRS suggesting that ghrelin-evoked gastric hyperemia could be an important

mechanism of the protective effect of this peptide in the rat stomach. This notion is based on the well-documented facts that an appropriate microcirculatory blood supply helps to orchestrate various lines of mucosal defense system in gastric mucosa. In addition, as mentioned before, ghrelin significantly increases the expression of mRNA for CGRP, which is known to increase the gastric mucosal blood flow. The mechanism by which ghrelin improves this gastric mucosal blood flow could be related to a direct effect of ghrelin on blood vessels due to a potent vasodilatory activity of this peptide. It is assumed that the direct protective effect of ghrelin can not be ruled out; however, no study has been yet undertaken to demonstrate that ghrelin exerts direct effects on vasculature.

Since the mechanism of gastric mucosal defense include NO that could be released from vascular endothelium, sensory nerves, or gastric epithelial cells, the hypothesis was tested that ghrelin-induced gastroprotection involving NO could originate from the activation of afferent sensory neurons by this peptide. The deactivation of rat primary afferent nerves, using a neurotoxic dose of capsaicin about 2 weeks before the stress experiment, aggravated WRS-induced gastric damage as compared to rats without capsaicin denervation and significantly reduced the GBF

when compared to that in animals with intact sensory nerves. Moreover, it has been demonstrated that such a capsaicin-induced deactivation of sensory nerves significantly attenuated the gastroprotective activity of central and peripheral ghrelin and completely abolished the ghrelin-induced rise in GBF. Moreover, the replacement therapy with exogenous CGRP, the major neuropeptide released from sensory afferent nerves, restored the protective and hyperemic activity of ghrelin against the WRS-induced gastric lesions (Figure 4). In addition, the expression of mRNA for CGRP, the major neuropeptide released from sensory afferent nerves, was enhanced in ghrelin-treated animals indicating that this major sensory nerve neuropeptide is essential for microcirculatory response and of crucial importance for the gastroprotective activity of ghrelin.

Involvement of sensory nerves in ghrelin-induced gastroprotection does not exclude the possibility that centrally applied ghrelin enhances the central parasympathetic outflow to the stomach and that also vagal efferent nerves are involved in gastroprotection afforded by centrally and peripherally administered ghrelin. It was proposed, for instance, that the inhibitory effects of ghrelin on gastric acid secretion require intact vagal pathways because vagotomy abolished the increase in gastric secretion induced by this

peptide. Indeed, vagotomy significantly attenuated the ghrelin-afforded gastroprotection and the accompanying rise in the GBF after its central and peripheral administration indicating that vagal pathway plays an important role in the mediation of the protective and hyperemic effects of this peptide against lesions evoked by stress. These data could be interpreted that ghrelin induced protection against damage induced by stress might be due to the stimulation of vagal cholinergic pathways that are involved in the recruitment of CGRP from afferent sensory nerves. Thus, evidence was provided that these protective and hyperemic effects of ghrelin may affect vagal nerves, the principal component of brain-gastrointestinal tract axis and involve cooperation between endogenous NO and sensory nerves releasing neuropeptides such as CGRP.

The finding that centrally applied ghrelin raised NO in stress model, is consistent with the observations that protective effects of ghrelin against ethanol can be attenuated by the pretreatment with L-NAME suggesting an involvement of NOS-NO pathway in the gastroprotective effect of ghrelin applied ICV. This excessive gastric NO production by ghrelin may originate from the upregulation of constitutive NOS (cNOS) rather than inducible NOS (iNOS) in the gastric mucosa. It seems likely that NO contributes to gastroprotection afforded by central and peripheral

Figure 4 The mean number of WRS-induced gastric lesions and the alterations in the gastric blood flow (GBF) in rats with intact sensory afferent nerves and those with capsaicin denervation with or without pretreatment with vehicle (Veh; control) and ghrelin ($20 \mu\text{g kg}^{-1}$ intraperitoneal). Please note that ghrelin-induced protection against WRS lesions and the accompanying increase in the GBF are almost completely abolished by functional ablation of afferent sensory neurons by capsaicin. These effects are further restored by the concomitant treatment of ghrelin with exogenous CGRP ($10 \mu\text{g kg}^{-1}$ subcutaneous) in capsaicin-denervated animals. Mean $\pm$ standard error of mean of 6–8 rats. Asterisk indicates a significant change compared to the value in vehicle-treated rats. Cross indicates a significant change compared to the value obtained in rats without capsaicin denervation. Asterisk and cross indicate a significant decrease as compared to ghrelin-treated animals with capsaicin denervation of sensory afferents.

ghrelin as proposed earlier for CCK and leptin, both also implicated in control of appetite and gastroprotection.

Therefore, it is concluded that ghrelin, besides its recognized function in the control of appetite, energy homeostasis, fat, and carbohydrate metabolism and gastrointestinal motility, could be considered as an important gastroprotective factor, expressed locally in the gastric mucosa in response to mucosal injury. This notion is supported by recent observations that mRNA for ghrelin is upregulated in the gastric mucosa exposed to WRS. Furthermore, it has been demonstrated that beneficial effect of ghrelin involves an activation of the capsaicin-sensitive sensory nerves in the gastric mucosa that are responsible for the increased production of CGRP in gastric mucosa exposed to WRS. This notion is in keeping with the previous studies demonstrating the importance of the activation of capsaicin-sensitive sensory nerves in the protection of gastric mucosa against acute gastric injury. The contribution of CGRP to the ghrelin-induced gastroprotection is further supported by the observation that the functional ablation of sensory nerves by capsaicin attenuated significantly the protective activity of ghrelin and completely abolished the rise in GBF induced by this peptide. The addition of exogenous CGRP to ghrelin in rats with deactivated sensory nerves restored the protection and accompanying rise in the GBF with the extent similar to that observed in ghrelin-treated rats with intact sensory nerves. These results indicate that sensory nerves, and their neuropeptides such as CGRP, are essential for microcirculatory response and of crucial importance for the gastroprotective activity of ghrelin.

Previous studies revealed that CGRP released in response to acute gastric mucosal injury leads also to increased production of NO due to activation of constitutive endothelial NOS. The exposure of rats to WRS that produced gastric lesions was associated with a significant downregulation of cNOS mRNA expression as compared to vehicle-control rats. The treatment with ghrelin of such WRS exposed rats, dose-dependently increased the expression of cNOS which reached the level of this expression comparable to that observed in the vehicle-control gastric mucosa indicating that ghrelin is capable of preventing the decrease in expression of cNOS mRNA caused by the exposure of this mucosa to WRS. The implication of NO in gastroprotection induced by ghrelin was further determined by employing of an inhibitor of NOS, L-NAME injected IP without or with addition of L-arginine, the substrate of NOS. The gastroprotective and hyperemic effects induced by ghrelin were significantly attenuated by L-NAME, but reversed by

addition to L-NAME of L-arginine. All these observations support the notion that NO plays a crucial role in the mechanism of gastric protection against WRS damage afforded by ghrelin.

Ghrelin Attenuates Inflammation and the Generation of Reactive Oxygen Metabolites

The beneficial effects of ghrelin on the protection of gastric mucosa against injury induced by WRS could be related to the suppression of free oxygen radicals and anti-inflammatory properties of this peptide. Recent studies indicate that ghrelin could be considered as an important mediator in the regulation of inflammation due to its anti-inflammatory activity. Pretreatment with ghrelin just before exposure to WRS and I/R caused a significant reduction in the mRNA expression of proinflammatory cytokine, TNF- α , confirming that anti-inflammatory effect of ghrelin contributes to the gastroprotection and hyperemia exhibited by this peptide. This mechanism seems to be of importance since the upregulation of TNF- α expression represent a central pathophysiological event in the mechanism of acute mucosal injury induced by stress. Further support for the potent anti-inflammatory effects of ghrelin is the fact that ghrelin inhibited the activation of NF κ B, which is considered as a critical signaling molecule in inflammation. Previous studies revealed that transcription factor NF κ B activation is involved in acute injury of stomach and other organs. In its inactive form, NF κ B is sequestered in the cytoplasm and bound by members of I- κ B family of inhibitor proteins. Phosphorylation of I- κ B by an I- κ B kinase complex leads to the translocation of NF κ B-p65 into the nucleus. Activation of NF κ B induces gene programs leading to transcription of factors that promote inflammation. Therefore, it is assumed that a potential mechanism whereby ghrelin could modulate inflammatory response is blocking of activation of NF κ B. This notion was confirmed by observation that ghrelin inhibits an activation of NF κ B in human endothelial cells *in vitro*.

Ghrelin not only prevents the acute gastric injury induced by WRS, but also accelerates the healing of these lesions. At 6 h after the end of standard 3.5-h WRS, a significant acceleration of healing of the WRS-induced lesions was observed in rats treated with ghrelin as compared to those treated with vehicle. The mechanism by which ghrelin could stimulate the healing of WRS-induced lesions is poorly understood. Previous studies demonstrated that the growth factors stimulating angiogenesis play a crucial role in the mechanism of healing process. The acceleration of healing of acute WRS-induced gastric erosions was

accompanied by the increased expression of hypoxia-inducible factor-1 α (HIF-1 α). The increased expression of HIF-1 α in the ulcerated mucosa leads to increased expression and activation of vascular endothelial growth factor (VEGF). For instance, the concomitant rise in the expression of HIF-1 α and VEGF was observed at day 6 following the combination of ghrelin and I/R and this was accompanied by a marked decrease of the gastric mucosal lesions produced by I/R. At 24 h after the end of WRS and I/R, an increase in expression of HIF-1 α , while resulting in downregulation of the VEGF expression was observed in ghrelin-treated animals. This early reduction of VEGF expression despite increased expression of HIF-1 α at 24 h after I/R injury or following mucosal recovery from WRS lesions could be attributed to the increased generation of free oxygen radicals and increased lipid peroxidation which can inhibit the activation of VEGF. It is known that healing of WRS and I/R injury involves an activation of antioxidant enzymes resulting in the inhibition of free oxygen species generation and subsequent enhancement in VEGF mRNA expression. This could, at least in part, explain significant increase in the expression for

VEGF mRNA at 24 h following WRS damage and at day 6 after I/R-induced gastric injury.

In summary, the administration of exogenous ghrelin applied by the ICV or IP routes that is accompanied by a significant increment in its plasma levels, exhibits dose-dependent gastroprotection against the WRS-induced gastric lesions. Ghrelin is effective not only in gastroprotection against WRS damage but also accelerates the healing of these lesions. Existing evidence indicates that these protective and hyperemic actions of ghrelin may affect brain-gastrointestinal tract axis and involve cooperation between endogenous PG, NO, and sensory nerves releasing neuropeptides such as CGRP (Figure 5). Ghrelin exerts a potent anti-inflammatory activity and inhibits activation of NF κ B, an important transcription factor, which seems to be an essential step in the formation of WRS injury. As CGRP and cNOS/NO system are activated in gastric mucosa of ghrelin-treated animals, it is assumed that these two factors could trigger the gastroprotective mechanisms and contribute to the maintenance of gastric mucosal integrity in experimental animals and possibly also in humans exposed to noxious agents and to adverse conditions such as stress.

Figure 5 Scheme of the proposed mechanisms involved in gastroprotective action of ghrelin against the formation of mucosal damage induced by stress. Besides recognized involvement of ghrelin in the regulation of food intake and appetite behavior, this hormone exhibits gastroprotective and hyperemic activity. Ghrelin-induced protection may involve the activation of brain-gastrointestinal tract (GI) axis via vagal and sensory innervation and interactions of this hormone with potent gastroprotective factors including nitric oxide (NO), calcitonin gene releasing factor (CGRP) released from sensory afferent nerve endings and gastrin, known to exhibit gastroprotective and ulcer healing properties. The gastroprotective activity of ghrelin is impaired by suppression of sensory afferent and vagal efferent activities by capsaicin denervation and vagotomy, respectively, confirming the importance of neural aspects in the mechanism of gastroprotection induced by this hormone. n.X, vagal nerve; PG, prostaglandin.

Anatomy and Structure

Physiology and Pharmacology

Neuron–Glial Cell Interactions

Glossary

<i>GABA</i>	Gamma-aminobutyric acid, the major inhibitory neurotransmitter in the brain.
<i>CR3</i>	Complement receptor 3, a marker for immune cells.
<i>ED1</i>	Product of the ectodermal dysplasia 1 gene, a marker of immune activation.

Introduction

In the past, neuroscientists concentrated almost exclusively on the electroactive components of the nervous system (neurons) because of their direct relationship to function, and neglected the nonelectroactive silent cells (glia), which outnumber them by

at least 10 to 1 in much of the nervous system. Classically, glia were named for and relegated to the status of glue responsible for binding together the more important neurons, although Ramón y Cajal and others classified them and made useful proposals about their functions. This neglect has now been partly redressed, and their important roles in development, in maintaining function in the face of physiological stresses, and in the response to injury and infection are now recognized.

Subsequent studies confirmed that there are basically three types of glial cells, namely:

1. Macroglia:
2. Astrocytes: cells with many processes and possible function
3. Oligodendrocytes: cells with few processes that form the myelin of myelinated nerve fibers
4. Microglia:
5. Macrophages: cells in white matter specifically activated in injury and degeneration

In addition to these glial cells, the normal brain also contains pericytes and perivascular macrophages. Pericyte processes partially cover the basement membrane of brain blood vessels in a way similar to those of astrocytes. Pericytes, however, express smooth muscle actin and are contractile. Both pericytes and perivascular macrophages express immune markers and have sentinel phagocytic functions.

Astrocytes are the most abundant cells in the mammalian brain and consist of (1) those located in white

matter (nerve fibers), which were termed fibrous astrocytes due to the large numbers of fibrils present in the cells, and (2) those located in grey matter (nerve cell bodies), which have fewer fibrils and were termed protoplasmic astrocytes. Despite the survival of this early attempt at classification, it is evident that many other intermediary forms exist.

Functions of Glial Cells

Macroglial cells, astrocytes, and oligodendrocytes all possess complex roles during development and, in the adult, involve complex interactions with neurons. Suggested supportive roles include metabolic supply of energy and other substrates (though the extent of this remains to be substantiated) and the ability to mop up released neurotransmitters (e.g., Glu and GABA) and ions (e.g., K^+ ions). Astrocytes are often closely associated with blood vessels. They regulate endothelial cell function and the permeability of blood vessels as well as producing many factors present in extracellular space, including growth factors and steroids that have multiple regulatory roles. Oligodendrocytes specialize in myelination in the central nervous system (CNS), a role confined to the Schwann cell in peripheral nerves. Such functions are critical to the function of the normal, healthy brain, but microglial cells become activated in pathological states and share many functions of the macrophages of the immune system. Such cells become cytotoxic during inflammatory responses and produce and respond to specialized proteins called cytokines, which mediate the complex interactions between microglia, astrocytes, and neurons, as well as infiltrating immune cells resulting from disruption of the normal blood-brain barrier during these pathological processes.

Specific biochemical markers of glial cells have contributed enormously to our understanding of the roles of these cells. Immunohistochemical studies in the 1970s identified a glial fibrillary acidic protein (GFAP) as an associated marker of fibrous astrocytes, though many GFAP-negative cells predominate in gray matter and various other markers for these have emerged.

In Vitro Studies of Glial Cells

In the 1980s glial cell culture techniques were developed in which the cell-specific markers enabled cell identity to be confirmed. Such *in vitro* methods have been coupled with imaging techniques to record changes in intracellular Ca^{2+} and other ions and patch clamp methods to study individual cells and those in more intact brain slice preparations.

Applications of these techniques have demonstrated that glial cells have complex signaling processes similar

to neurons. Compared to neurons, glial cells generally have a more negative resting membrane potential due to a higher permeability to potassium. Glial cells therefore usually do not produce action potentials and remain passive (or silent) during intracellular recording, though more recent studies using patch clamping techniques have identified complex membrane properties. In addition, glial cells in culture, especially astrocytes, have been widely used to characterize membrane voltage-dependent channels (predominantly potassium channels and also low densities of sodium and calcium channels).

Many pharmacological and molecular studies indicate that glial cells possess a variety of transmitter, hormonal, and other receptors, though most glial cells appear to communicate with each other through specialized gap junctions rather than chemical synapses. This enables cytoplasmic exchange of many molecules, and such syncytial coupling may explain the lack of active membrane properties of glia cells *in situ*.

Anatomy and Structure

The staining techniques of Golgi (first described in 1885) provided the means for the earliest identification and morphology of neuroglial cells and neurons in the vertebrate nervous system.

Astrocytes

Astrocytes are the most abundant cells in the mammalian brain but are somewhat polymorphic. Those close to nerve fibers (white matter) are termed fibrous, since they are relatively hypertrophic with prominent intermediate filaments. The less prominent astrocytes associated with nerve cell bodies and synapses (gray matter) are termed protoplasmic, although intermediate forms exist, such as those associated with blood vessels.

All these share a common phenotype, with uniform expression marker proteins such as aldolase 3, but expression of others such as S-100 and GFAP may vary markedly. The most extreme instance of this phenotypic diversity within astrocytes is represented by the adult neuronal precursor cells in the subventricular zone, which have most of the characteristics of the astrocytes seen elsewhere yet retain the ability to dedifferentiate and form neurons by asymmetrical division.

Oligodendrocytes and Schwann Cells

Similarly, oligodendrocytes, which were found in early anatomical studies to produce the myelin sheath in the CNS, are analogous to the Schwann cells associated with peripheral neurons; they also exhibit

structural diversity and heterogeneity, including possible distinct perivascular as opposed to perineuronal oligodendrocytes. Although various subtypes have been identified, the growth and development of oligodendrocytes and their specific interaction with the neuron have been less well studied than those of the astrocyte.

Schwann cells function to protect peripheral neurons and nerve fibers from the surrounding tissues, are separated by a basal lamina, and are broadly of two types. The major group is ensheathing Schwann cells that are associated with unmyelinated nerve axons in parts of the autonomic and sympathetic nerves and dorsal root ganglia, where they offer strength and protection. Better known are the cells that form myelin sheaths around larger, fast-conducting nerve fibers (myelinating Schwann cells). The myelin sheath occurs in blocks with intervening nodes of Ranvier that possess high concentrations of potassium ion channels. This segmental arrangement, as well as providing important neuronal insulation, allows conduction of ionic currents within the enclosed fiber and facilitates saltatory (jumping) conduction along the fiber, resulting in a marked increase in conduction velocity of impulses. Recent research has strengthened the long-held view that Schwann cells are also metabolically active in facilitating regeneration processes and thereby enable peripheral nerve fiber recovery from injury, a capacity absent in central neural processes that lack Schwann cells. This prompted studies that have shown that in some situations it is feasible to experimentally transfer populations of Schwann cells into the CNS and thereby activate brain axonal regeneration.

A special type of CNS glial cell is the ependymogial (radial glia) cells, which line the ventricular spaces of brain. These are specially modified astrocytes of a characteristic bipolar structure with a ciliated apical pole protruding into the cerebrospinal fluid (CSF). In many vertebrate species, some of these cells include specialized sensory epithelia that develop mechanoreception (e.g., organ of Corti and vestibular organs). They also include tanycytes, which have a specialized role in the transportation of molecules between local blood vessels and brain circumventricular organ regions of the ventricular system; they are of particular importance in regions of the hypothalamus for the distribution of neuropeptide hormones. Other radial glial cells have important roles in development and demonstrate transitory existence.

Microglia

Microglial cells in the brain may outnumber nerve cells, and in the adult become particularly important

in pathological states. Those present in the normal (nonpathological) brain are termed resting or ramified (many branched appearance) microglia, while activated (or reactive) microglia cells may be nonphagocytic or become phagocytic microglia in fully activated pathology. Microglia derived from the systemic immune system invade during development and take up a quiescent resting morphology, their fine processes establishing nonoverlapping territories that cover the whole brain. A number of immune marker proteins such as CR3 can be used to identify resting microglia, and when activated they express a wide variety of markers characteristic of immune signaling and cytolytic functions such as ED1, interleukins, and nitric oxide synthase.

Physiology and Pharmacology

Ion Channels and Receptors

With their many processes surrounding synapses and cell bodies, astrocytes are well placed to dominate and regulate extracellular homeostasis, especially since they express a variety of ion channels, including potassium (K^+), sodium (Na^+), calcium (Ca^{2+}), and ligand-gated channels. The latter reflects the local pattern of neuronal neurotransmitter types, and all have largely been studied using primary astrocytes in culture and patch clamp techniques. Similarly, whole cell patch clamp methods have been applied to *in situ* preparations using hippocampal or other brain slices. These studies have identified many types of K^+ channels in astrocytes, indicating an important function of these cells in the regulation of extracellular levels of this ion, consistent with the notion that maintaining K^+ homeostasis is an important function of astrocytes.

Astrocytes, oligodendrocytes, and Schwann cells also possess voltage-gated Na^+ and Ca^{2+} ion channels, but at much lower densities than those in neurons. This causes some difficulties regarding understanding their precise function, since there are insufficient levels for action potentials to be generated. With respect to Schwann cells, some authors have suggested that the ion channels may be a local store of channels that can be passed to neighboring neural axons, since they share similar properties, but this remains to be directly demonstrated. Na^+ channels may also produce sufficient Na^+ exchange for the activation of astrocyte Na^+/K^+ -ATPase activity. Like with many other cells, modulation of glial intracellular Ca^{2+} may be an important signaling mechanism, since Ca^{2+} influx is activated by various stimuli, although the roles of calcium in astrocytes and other glia remain to be clarified.

Such ionic changes may be regulated by ligand-gated channel receptors, including GABA_A, that also

occur in the membranes of cultured astrocytes. Astrocytes also express high-affinity carrier systems for various neurotransmitter-like molecules, especially amino acids (e.g., Glu and GABA), and amino acid uptake into these cells may well contribute to the physiological regulation of these transmitter synapses as well as offer possible cytotoxic protection from such amino acids. Recent work suggests similar regulation of arginine, which is the precursor of nitric oxide, now considered a fundamental signaling molecule in neural tissues.

Astrocytes also contribute to extracellular ionic homeostasis by sequestering potentially neuronotoxic metals such as mercury and aluminum.

Metabotropic Receptors

Metabotropic (G-protein-coupled) receptors are also present in glial cell membranes, and there is good evidence for functional roles for glutamatergic (Glu), GABA_B, cholinergic (ACh), serotonergic (5-HT), adrenergic (NA), and various peptidergic (including angiotensin II, somatostatin, endothelium peptides, and substance P) receptors in cultured astrocytes, as shown by binding studies, the use of receptor-selective antibodies, and *in situ* hybridization methods. Similarly, biochemical analyses of second messenger systems, such as cyclic AMP, as well as cytosolic ionic changes, have demonstrated the pharmacological properties of such receptors. Similar receptors for hormones and growth factors are also present.

Gap Junctions

Gap junctions are predominant intercellular cytoplasmic communications between glial cells, though they also occur in other cells, including neurons. They consist of specialized membrane protein channels that enable the flow of inorganic and organic molecules between cells, usually consisting of six similar connexin molecules. Various types of connexin have been identified as products of a specific family of genes and have been associated with specific glial cells and neurons.

Intercellular communication via gap junctions provides a mechanism whereby the whole local population of astrocytes can make a coordinated contribution to maintaining ionic homeostasis in the face of physiological or pathological stress. The potential depolarizing effect of an accumulation of extracellular potassium during transiently high levels of neuronal activity can be minimized by its movement into and distribution between astrocytes within the active region until activity returns to normal. In addition, these astrocytic end feet that are in contact with capillaries show a high level of expression of

aquaporins, which may play a role in bulk movement of water within the brain.

Neuron–Glial Cell Interactions

Metabolism

The physical location of astrocytes between metabolic supply via the vasculature and metabolic demand in the neuron, combined with their unique possession of an energy reserve in the form of glycogen granules, is a clear indication of their potential role in energy metabolism. Furthermore, since astrocytes express glutamine synthetase, which is lacking in neurons, there is important metabolic cycling of glutamate and glutamine between neurons and glia. In addition to the considerable physiological importance of this cycle, astrocytic glutamine synthetase also plays an important role in defending the brain against hyperammonemia. Perivascular astrocytes are also the first casualties in hepatic encephalopathy.

Although there is no analogous compartmentation of the enzymes involved in glycolysis, it has been proposed that astrocytic conversion of glucose to lactate is followed by transfer of this lactate to neurons (the lactate shuttle hypothesis) and that this is the major pathway for glycolysis. There is recent evidence that the glycolytic response seen within 10 s of neuronal activation is specifically localized within astrocytes. Circulating lactate (elevated during fatiguing muscle activity) can also effectively substitute for glucose as an energy supply in the brain.

While astrocytes have been the primary focus of research, oligodendrocytes also respond metabolically to increased demand (as after traumatic myelin damage) in a complex manner with changes appropriate to the activation of sphingoglycolipids for myelination.

Neurotransmitter Inactivation

Astrocytes are closely associated with neuronal synapses in the CNS and are equipped with the means to degrade most neurotransmitters. Work in the late 1960s showed that various transmitters flowing out of the synaptic cleft are taken up and inactivated by glial elements. However, the question remains regarding the physiological importance of such processes during normal transmitter function, and it is possible that such processes function as a protective process during excess transmitter release and/or during pathological states. However, it is well established that astrocytes participate in the glutamate-glutamine cycle, in which metabolized transmitters can be taken up by the astrocyte and returned to neurons as a precursor.

Response to Injury: Microglia and Inflammatory Disease and Neuroglia and Stress

Response to local injury Although the brain does not participate in the normal systemic response to inflammation, the local presence of abnormal material (e.g., plasma proteins, cell debris, bacteria) or cytokines in the brain extracellular space activates both sentinel microglia and astrocytes. These recruit circulating neutrophils and monocytes, which arrive by vascular transcytosis, and all begin the process of cell killing and removal of debris. In addition to producing pro-inflammatory cytokines, activated microglia themselves become phagocytic. This local inflammation is normally self-limiting, and results in a glial scar that persists long after the initial damage has resolved. During inflammation, the normally tight blood–brain barrier becomes open to small molecules, under the influence of locally secreted cytokines and vascular endothelial growth factor. Normal vascular integrity is restored as the inflammatory process dies down. The later phase of the inflammatory process is associated with debris removal and replacement of nonneuronal elements, after which recruited macrophages leave the brain. However, the persistence of hypertrophic astrocytic processes within the scar severely limits the degree of axonal regrowth that is possible, although surviving axons passing through lesions can be remyelinated. In contrast, peripheral nervous system Schwann cells activate in a manner analogous to that seen during early development and facilitate axonal regeneration. In the future it may be possible to overcome the inhibitory influence of astrocytes and oligodendrocytes on axonal regrowth by blocking astrocyte-derived signaling molecules.

Local autoimmune reactions are seen in some disease states, most notably multiple sclerosis. In multiple sclerosis, apparently random, but most commonly periventricular, oligodendrocytes are targeted with primary demyelination and secondary neurodegeneration. The process of focal vascular infiltration and cytolysis progresses slowly, either continuously or, more commonly, at irregular intervals (the relapsing remitting form). The acute inflammatory process never extends beyond these focal areas, although magnetic resonance studies do show minor abnormalities in otherwise normal white matter. The precipitating factors that direct the immune system to what is to become a new focal area of damage are unknown, but may be minor vascular lesions that would be asymptomatic in a person without autoantibodies. A similar condition (relapsing experimental allergic encephalitis) can be produced in experimental animals autoimmunized with myelin basic protein.

Response to systemic injury and stress Glial cells express a variety of hormonal and growth factor receptors, which seem to be critical during development as well as during stress-induced injury or disease. Evidence indicates that thyroid hormones, especially T_3 , which are well known for their requirement in the maturation of neurons, also bind to stem cell astrocyte nuclei and regulate glial differentiation during development. A number of developmental neurotoxins are known to act by targeting glial proliferation, and maternal stress can have marked and irreversible effects on brain maturation.

More significantly, it is now well documented that astrocytes and oligodendrocytes synthesize many steroid hormones during development, while adult cultured cells have been shown to express receptors for several steroids, including estrogen, progesterone, glucocorticoids, mineralocorticoids, and androgens. Moreover, recent developments indicate that many such steroids elicit rapid nongenomic effects on both neuron and glial cells via membrane-bound receptors in addition to the established intracellular and nuclear genomic receptors known to activate RNA and protein synthesis.

The term neurosteroid describes the neuroactive steroids that are synthesized and released from glial cells and act as local neuromodulators in the brain. Such local steroids may be modulated in turn by the rise of hormones in the circulation during stress. For example, neurosteroids such as dehydroepiandrosterone (DHEA) alter in stress and during depression and may inhibit or reverse the stress effects of corticosteroids and other stress- or drug-induced behaviors. Furthermore, recent evidence suggests that cortisol-induced loss of brain hippocampal neurons may be attenuated by DHEA; an interesting possibility is that glial steroids may function as part of a neuroprotective mechanism.

The adult brain participates in systemic inflammation or trauma by producing sickness behavior (fever, loss of appetite, social withdrawal, and inactivity). This is thought to be mediated via the few small open barrier brain areas (notably the area postrema) that lack a blood–brain barrier and have resident macrophages that can respond directly to circulating cytokines and then signal to activate resident microglia elsewhere in the brain.

There is also some evidence that residual semi-activated states in resident microglia from prior brain damage or the accumulation of minor damage seen in normal aging may render otherwise normal brain areas sensitive to systemic cytokines. This has been suggested as a mechanism whereby systemic infections may precipitate a sudden deterioration in chronic neurodegenerative conditions such as Alzheimer's disease.

A number of studies have reported generalized increases in blood–brain barrier permeability in animals subjected to stress. Of those studies showing increased leakage into the brain parenchyma, several have not proved reproducible, and others did not allow sufficient time for markers to be cleared from the normal brain vasculature. The better methodologies have shown no evidence for blood–brain barrier compromise with stress, other than in extreme hypertension. However, in the case of dural blood vessels on the brain surface, there is some evidence that stress can lead to increased permeability. This stress effect, in rats and mice, is mediated by trigeminal activation of resident dural mast cells, and the effect may be relevant to the genesis of migraine headaches.

Introduction

Effects of Stress on Different Memory Systems

Clinical Implications

Summary and Conclusion

*Procedural
memory*

Different forms of nonconscious (implicit) long-term memories that express themselves through changes in performance. These forms of memories are largely independent of the medial temporal lobe memory system.

*Working
memory*

A system for temporarily (short-term) storing and managing information. This system is dependent on regions of the prefrontal cortex.

Glossary

*Classical
conditioning
Declarative
memory*

A form of learning caused by the association (or pairing) of two stimuli.

The conscious (explicit) long-term memory for events or facts, mediated by the medial temporal lobe.

*Glucocorticoids
(GCs)*

Steroid hormones secreted from the adrenal cortex in response to stress. Cortisol and corticosterone are naturally occurring GCs in humans and animals.

Meta-analysis

A statistical procedure used to pool the results of multiple studies investigating a particular effect. This approach leads to a quantitative summary of a specific field of interest.

Introduction

Everyone has experienced instances of stress influencing his or her memory. There are situations in which we are unable to retrieve prior well-learned information, an example of how stress might interfere with our memory. In contrast, we remember very well specific embarrassing, shameful, or frightening events from the past; this is an example of how stress can enhance our memory. Finally, there are situations of chronic stress or stress associated psychiatric disorders that are characterized by hypo- or hyperamnesia. This article provides a brief and selective overview of what is known about the role of GCs in mediating

some of these effects. Advances in the field of psychoneuroendocrinology within the past few years have contributed substantially to a more differentiated and balanced view of the effects of stress hormones on memory in animals and humans.

Interaction with a stressor leads to a cascade of neuroendocrine stress responses designed to facilitate adaptation to the changing demands. The hypothalamic-pituitary-adrenal (HPA) axis, together with the sympathetic nervous system (SNS), is one of the most important systems in this respect. The hypothalamus activates the HPA axis in response to input from several other brain regions. Corticotropin releasing hormone (CRH) and vasopressin reach the pituitary through the portal blood system, which leads to the secretion of adrenocorticotrophic hormone (ACTH). In response to ACTH release from the pituitary, the adrenal secretes GCs. In most laboratory rodents (rats and mice) corticosterone dominates, whereas in humans cortisol is the main adrenal GC. GCs, as lipophilic steroid hormones, enter the brain relatively easily and exert multiple effects in regions throughout the brain. These effects are often mediated through the binding to the two receptors for the hormone: the mineralocorticoid receptor (MR) and the glucocorticoid receptor (GR). These two receptors differ in their affinity for cortisol (with the MR having a much higher affinity) and also in their localization in the brain. In addition, GCs can exert rapid nongenomic effects by influencing ion channels or neurotransmitter receptors at the membrane level. We emphasize that CRH, vasopressin, and ACTH can, on their own, influence cognition; the focus of this article, however, is on the effects of GCs on the memory of humans and animals.

To date, there is a substantial, almost overwhelming, literature on stress and memory. A PubMed search conducted with the two search terms stress and memory produced more than 3000 hits. Even a more focused search using glucocorticoids and memory as search terms still resulted in almost 400 hits. In order to provide a structured overview of this large and rapidly growing field, I use the concept of multiple memory systems in the brain to guide the reader through this jungle. Within each discussed memory domain, animal and human data are discussed. Acute stress effects are described, followed by chronic effects.

Effects of Stress on Different Memory Systems

There is a general agreement that there is not a single memory system in the brain but multiple interacting memory systems. Abundant literature exists on this topic, and it is not the goal of the current review to

provide an in-depth overview of different models and ideas; the important question of the comparability of different memory systems in different species is not addressed here either. I focus instead on declarative or explicit long-term memory because this domain has been, until now, investigated most intensely with respect to stress effects. In addition, I briefly outline the findings for procedural memory, working memory, and conditioning (or associative learning); these three memory systems have been sparsely investigated, at least in humans.

Declarative Memory

Acute effects Declarative memory is the explicit storage of facts and events, which can later be intentionally retrieved. It is a relational and flexible memory system. This type of memory is tested in the laboratory with word lists, paired associates, or short stories in humans. In animals, spatial maze tasks are used most often, the most famous one being the Morris water maze (MWM). Long-term memory can be further divided into different memory phases: acquisition (or initial learning), consolidation (or storage), and retrieval (or recall). For the successful completion of declarative tasks, an intact medial temporal lobe region (the hippocampus and surrounding cortical structures) is essential for the acquisition of the task. The role of the hippocampus in retrieval is under debate, and it might fulfill a time-limited role only. Especially in humans, it is the prefrontal cortex regions that are of great importance for (effortful) retrieval. The literature regarding the effects of stress on declarative memory is quite diverse and confusing, with groups reporting enhancing as well as impairing effects of GCs on this form of memory. However, it has become apparent that this is largely due to the fact that the different memory phases are modulated by GCs in an opposing fashion.

GCs enhance memory consolidation, and this aspect represents the adaptive and beneficial mode of GCs central nervous system action. [Figure 1a](#) depicts the chain of events underlying this phenomenon. This process has been conceptualized as the beneficial effects of stress within the learning context or intrinsic stress, emphasizing that a stressful episode is remembered better. This effect is mediated by the action of stress-released GCs on the hippocampal formation, and it is very well documented in animals. Studies by Roozendaal and McGaugh showed that adrenergic activation in the basolateral amygdala (BLA) appears to be a prerequisite for the modulating effects of GCs on other brain regions (e.g., the hippocampus). Lesions of the BLA, as well as β blockade, abolish the enhancing effects of posttraining GC administration.

Figure 1 Schematic diagram of the cascade of events underlying the effects of GCs. a, Positive effects on long-term memory consolidation; b, negative effects on long-term memory retrieval. GC, glucocorticoid; HPA, hypothalamic-pituitary adrenal; SNS, sympathetic nervous system.

Although the enhanced memory consolidation is adaptive and beneficial, this process appears to occur at the cost of impaired retrieval (see [Figure 1b](#)). Using a 24-h delay interval, deQuervain and colleagues were the first to show that stress or GC treatment shortly before retrieval testing impairs memory retrieval in rats in the MWM. Further studies revealed that, again, an intact BLA and adrenergic activation appear to be necessary for the occurrence of this negative GC effect. Roozendaal summarized these findings as indicating that stress puts the brain into a consolidation mode, which is accompanied by impaired retrieval. Such a retrieval reduction might facilitate consolidation by reducing interference.

In humans, the literature on the acute effects of cortisol on declarative memory is somewhat divergent. Few studies reported beneficial effects, some reported negative effects, and several others found no acute effects. We recently conducted a meta-analysis in order to provide a quantitative summary of the current state of the field. The results supported the model derived from animal studies showing that cortisol impairs memory retrieval. Similar observations have been made in humans who were exposed to a psychosocial laboratory stressor shortly before retrieval testing took place.

To date, the beneficial effects on consolidation could not be clearly established using a meta-analysis, which in part might reflect a power problem. At least some studies, using emotionally arousing learning material and a sufficiently long retention delay in order to assure that GCs can influence consolidation

and in addition are back to baseline at the retrieval testing, observed enhanced memory consolidation for emotionally arousing material.

Interestingly, the beneficial effects on consolidation as well as the impairing effects on retrieval in humans are more pronounced for emotionally arousing material. This observation fits nicely with the observation in animals that GCs can exert effects on memory only in the presence of adrenergic activity in the amygdala. This arousal could be the result of specifics of the learning material and/or specifics of the testing conditions.

In the meta-analysis, time of day appeared as a second modulatory factor. Studies that administered cortisol before initial acquisition observed impairing effects on memory when they were conducted in the morning, a time of high endogenous cortisol levels in humans. In contrast, studies in the evening were more likely to observe beneficial effects. This supports an inverted U-shaped function between cortisol levels and memory in humans with both too low and too high levels at the time of acquisition being associated with impairments, especially when retrieval is tested at times when cortisol levels are still elevated.

In sum, studies in animals and humans converge on the idea that GCs acutely enhance memory consolidation of emotional arousing material while impairing memory retrieval. In addition, within this framework, emotional arousal and a nonlinear dose-response relationship are important modulatory variables.

Cortisol also influences declarative memory consolidation during sleep. Here the relationships appear

to be different than in the daytime. Low cortisol levels during the first half of the night are a prerequisite for a sleep-induced enhancement of declarative memory consolidation. Moreover, blocking the rise in cortisol levels, which typically occurs during the second part of the night, leads to enhanced emotional memory facilitation.

The interesting issue of individual differences in responsiveness to GCs has received little attention so far. Such differences might be able to account for some of the variance observed within as well as between studies. Individual differences could reflect genetic factors, differences in tissue GC sensitivity, or differences in lifetime cortisol exposure. Attempts to characterize subgroups with high versus low cortisol sensitivity could be one important venue for future research.

Chronic effects The picture is different for more chronic effects as a result of prolonged stress or GC treatment – here negative effects prevail. Chronic stress in animals has repeatedly been shown to result in impaired spatial-memory performance. The neurobiological underpinnings of those effects are still under debate. Stress-induced dendritic atrophy (or dendritic remodeling) in the hippocampus is one possible mechanism for the negative effects of chronic stress on spatial memory in rodents. However, several additional mediators such as reduced neurogenesis and dysregulation of several catecholamines have to be considered. Recent studies demonstrated substantial plasticity in the adult rodent brain. For example, stress-induced dendritic atrophy appears to be reversible.

Interestingly, the negative effect of chronic stress on spatial memory might occur only in male rats and not in females. In fact, similarly, acute stress appears to impair spatial memory only in males. The area of sex differences in response to stress is an important and still relatively neglected field. However, authors who went through the extra effort of studying male and female animals have often observed quite striking sex differences in the effects of stress on a wide range of target systems. These observations in combination with evidence for sex differences in emotional memory lateralization and sex differences in the effects of adrenergic manipulations on emotional memory emphasize that caution should be used when generalizing findings obtained in one sex to predict responses in the opposite sex.

In humans, the effects of chronic long-term GC treatment cannot, of course, be studied experimentally due to ethical considerations. Studies that administered GCs for several (3–10) days observed declarative memory impairments. Moreover, studies of patients receiving GC therapy and studies of hypercortisolemic

Morbus Cushing patients observed reduced declarative memory performance, which was associated with hippocampal atrophy. Some treatment studies in Cushing patients suggest that hippocampal atrophy in Cushing is reversible, which fits the observations in rodents previously mentioned.

Aging leads to alterations of HPA activity. Basal activity seems to increase and negative feedback is less efficient. Animal studies have suggested that enhanced HPA activity is associated with poorer memory. In older, otherwise healthy humans, several observational studies also reported associations between elevated or rising cortisol levels and declarative memory impairments. Whether these associations are specific for declarative memory or are, in fact, broader (also including working memory or attention) is currently under debate. Obviously all these human studies do not allow a clear cause and effect interpretation. Moreover, in most of these studies, the acute effects of cortisol cannot be differentiated from the chronic effects. In addition, the possible structural correlate of these hormone-performance associations remains to be firmly established. Hence, the possible association between rising cortisol levels and atrophy of the hippocampus is still not sufficiently understood, and the current empirical situation is somewhat mixed.

Finally, it has to be reiterated that other hormonal influences also might be important. With respect to aging, elevated cortisol levels could be part of the metabolic syndrome. Other aspects of this nonfavorable endocrine condition are impaired glucose tolerance and hypertension. These alterations have also been associated with memory impairment during aging, so future studies on this issue should consider taking a broader set of neuroendocrine measurements.

Procedural (Nondeclarative) Memory

This implicit and automatic form of (long-term) memory is not dependent on the medial temporal lobe. The brain areas involved depend on the specific content of the learning material. The neocortical areas, as well as the cerebellum and the basal ganglia, are involved in procedural memory. This is assessed in the laboratory with priming tasks (e.g., word-stem priming) or with skill-learning tasks (e.g., mirror tracing). In the few studies that used such tasks in the context of stress or GC research, a modulating effect of GCs was not observed, thus supporting the assumption that this memory form is not strongly influenced by GCs.

Working Memory

Working memory refers to the ability to store for the short term and manipulate material. This framework

has replaced the older notion of short-term memory and emphasizes the active processing capacity of this system. Neuroanatomically, this function has been linked to the prefrontal cortex (PFC). There are a large number of GRs in the PFC, but, in contrast to the effects of GCs on the hippocampus, the effects on the PFC are less well characterized. Acute impairing effects on working memory have been reported in animals and in some studies in humans, but the results have been somewhat inconsistent.

Regarding the chronic effects of GCs on working memory, impaired performance has been reported in animals and humans. In animals, chronic stress was associated with dendritic atrophy in prefrontal regions, which was reversible. In humans, elevated basal GC levels have been associated in some studies with smaller PFC volumes. The PFC is, of course, not only involved in working memory but also in executive functions. These domains have not been well investigated in humans with respect to GC effects and additional research efforts are still needed.

Classical Conditioning (Associative Learning)

Classical conditioning is one of the most basic forms of learning, and it can be demonstrated in snails, fruit flies, rodents, and humans. The brain regions involved depend on the specific stimuli used and the timing of the conditioned stimulus (CS)–unconditioned stimulus (UCS) association. For example, the cerebellum is involved in simple eyelid conditioning, whereas the amygdala is critical for fear conditioning and the hippocampus is important for contextual conditioning and trace conditioning. In rodents, the effects of stress on conditioning has been studied repeatedly. For eyelid conditioning, Shors and coworkers observed that stress enhanced conditioning in male rats. This was true for delay as well as trace conditioning. Interestingly, they observed the opposite effect in female animals – stress impaired conditioning. These findings are the opposite of the effects of acute stress on spatial memory, in which stress enhanced memory in female rats while impairing it in males. Although the enhancing effects of stress or GCs have been observed for fear conditioning, the issue of sex differences has not been addressed systematically. With respect to chronic stress, enhanced fear conditioning in the presence of hippocampal dentritic atrophy has been detected. In humans, classical conditioning has not been studied intensively in the context of neuroendocrine stress research; however, the available studies also observed sex differences. Because this form of learning and memory is of relevance for several psychiatric disorders, more research appears to be necessary.

Clinical Implications

The basic-science studies discussed thus far are also of substantial clinical relevance. For example, patients with posttraumatic stress disorder (PTSD) have been reported to show reduced basal cortisol levels, which is probably due to an enhanced negative feedback of the system. Recent small-scale clinical studies suggested that cortisol treatment shortly after the trauma might help to prevent PTSD. Moreover, even patients with chronic PTSD appear to benefit from a low-dose cortisol treatment. For such patients, the impaired emotional memory retrieval, in combination with an enhanced and more elaborate (place and time) reconsolidation, might help to reduce the core symptoms of the disorder, illustrating that basic science studies in the field of stress neuroendocrinology can help us to understand and possibly treat major psychiatric disorders.

Summary and Conclusion

Research over the past decade has substantially helped us gain a better understanding of the effects of GCs on memory. It is obvious that a more differentiated picture of stress effects on memory has evolved and that oversimplifications such as “stress impairs memory” are no longer supported by the existing literature. Increases in GCs induced by acute stress enhance memory consolidation but impair memory retrieval. These impairing effects of stress-induced GC secretion might hinder us in performing well in an important exam or at an important job interview. In addition, GCs also appear to reduce the amount of items that can be stored in working memory, but this is less well documented than the effects on declarative long-term memory. Interestingly, there is now convincing evidence that adrenergic activation in the amygdala is a prerequisite for several acute effects of GCs on memory. This activation can be induced either through the cognitive task itself, through the test situation (e.g., novel unfamiliar environment), or through the test material (e.g., emotional slides).

Substantial sex differences have been observed in several animal studies, but evidence in humans is still sparse. The direction of the effect appears to be task-specific. More knowledge about sex differences should, in the long run, help us understand sex differences in stress-associated disorders. Future studies need to investigate whether these sex differences are related to differences in the neuroendocrine stress response or differences in the response of the brain to endocrine stress messengers.

Chronic stress or chronic GC treatment has mostly negative effects on the brain and on the body. These observations are relevant to psychiatric disorders as well as to the aging process. However, it is encouraging that recent research has repeatedly observed evidence for preserved plasticity and structural remodeling once the stress has ceased or GCs return to normal levels.

Especially rewarding for all basic-science research that has been done on stress is that already several clinical applications have been implemented or are on the horizon.

Characteristics of Feedback in the Hypothalamic-Pituitary-Adrenocortical Axis

Site(s) of Negative Feedback in the Hypothalamic-Pituitary-Adrenocortical Axis

Glossary

<i>Adrenocorticotrophic hormone (ACTH)</i>	A hormone made in corticotroph cells of the anterior pituitary; it stimulates the synthesis and secretion of corticosteroids from the adrenal cortex.
<i>Arginine vasopressin (AVP)</i>	A hormone that, when cosecreted with CRH, potentiates ACTH release.
<i>Corticotropin releasing hormone (CRH)</i>	A hormone synthesized in the hypothalamus; it stimulates ACTH synthesis and secretion from anterior pituitary corticotrophic cells.
<i>Dexamethasone</i>	A potent synthetic glucocorticoid that does not bind to transcortin (corticosteroid-binding globulin, CBG).
<i>Glucocorticoid receptor (GR)</i>	Low-affinity intracellular corticosteroid receptor that prefers dexamethasone, cortisol, and corticosterone.
<i>Limbic system</i>	A system of neural structures (amygdala, bed nuclei of the stria terminalis, hippocampus, septal nuclei, and hypothalamic and midbrain cell groups) that subserve the emotional and other associative memory, determining overall responsiveness to stressors.
<i>Mineralocorticoid receptor (MR)</i>	High-affinity intracellular corticosteroid receptor that selectively binds aldosterone, corticosterone, and cortisol.
<i>Paraventricular nucleus (PVN)</i>	Hypothalamic site of neuronal synthesis of CRH and AVP, which are secreted from axonal endings in the median eminence to act on pituitary corticotrophs.
<i>Stressors</i>	Stimuli that challenge the physical or psychological stability of the organism and cause the activation of the hypothalamic-pituitary-adrenal axis.
<i>Transcortin (CBG)</i>	A high-affinity binder for cortisol and corticosterone made by the liver; it reversibly binds corticosteroids in the circulation; also called corticosteroid-binding globulin.

Negative feedback inhibition by adrenal glucocorticoids is the means by which the brain is informed that the pituitary ACTH-secreting cells and adrenocortical fasciculata cells have done its bidding. However, a great deal of flexibility is required for an effective feedback system to serve its appropriate function. Thus, there are various time domains and mechanisms by which the glucocorticoids act to inhibit further brain-induced stimulation of the hypothalamic-pituitary-adrenocortical (HPA) axis, the different sites at which the steroids act, and the state-dependent modifications of the brain response to the feedback action of the steroids. The net result of this seeming complexity is a spectacularly functional feedback system that maintains glucocorticoid levels at values appropriate for the physiology of the organism at most times.

Characteristics of Feedback in the Hypothalamic-Pituitary-Adrenocortical Axis

The wide variation in total circulating corticosteroid levels, from the low nanomolar range during the daily circadian trough to the micromolar range during stress, provides a problem for feedback regulation by corticosteroids; the solution is to use two receptors of differing affinities to regulate the brain activation of the adrenocortical system. In addition, there are three temporal domains for the inhibitory effects of corticosteroids and the brain also manages to modify the apparent efficacy of the negative feedback effects of corticosteroids under persistently stressful conditions, thus maintaining an HPA axis that is responsive under conditions in which circulating corticosteroid levels are higher than the usual set point.

Two Receptors Mediate the Feedback Effects of Glucocorticoids

Figure 1 indicates the problem that must be solved by a corticosteroid feedback system in order to control accurately the activity of the HPA axis under circadian and stressful conditions. During the trough of the basal rhythm, total cortisol levels range between 50 and 100 nM. Because at low values ~99% of this represents cortisol bound to CBG, the free cortisol levels that can diffuse from the vascular compartment into the interstitial fluid to bathe cells range between ~0.5 and 1.0 nM. By contrast, at the peak of the circadian rhythm and after stress, total cortisol ranges up to micromolar concentrations and free

Figure 1 The two-receptor system that provides feedback information to the central HPA axis about adrenocortical performance. A hypothetical normal circadian rhythm in total plasma cortisol (CBG-bound and free) in humans. The dark bar on the abscissa represents the hours of darkness and sleep. The peak occurs just prior to awakening and the beginning of the daily activity cycle. The trough (MR occupancy) occurs early in the hours of sleep and inactivity before values rise again. Stressor-induced increases in cortisol can reach micromolar concentrations. Clearly, if GRs are occupied, MRs are as well. The estimated occupancy of MRs and GRs by free steroid at the various levels of total steroid is shown on the right.

cortisol levels approach 100–300 nM or even higher. Because receptors characteristically bind hormone over a 100-fold range, it is clear that a single receptor for cortisol cannot control the range of cortisol concentrations required during the normal physiological excursions of the HPA axis. The solution is the use of two receptors of differing affinities to inform the brain of adrenocortical activity.

1. The MR is a high-affinity receptor (K_d 0.5–1 nM) that has roughly equally high affinity for aldosterone, cortisol, and corticosterone. In cells that are selectively responsive to aldosterone, such as the principal cells of the renal nephron, there is an enzyme (11- β -hydroxysteroid dehydrogenase type II) that oxidizes the 11-hydroxyl groups of cortisol and corticosterone to the inactive 11-keto form. Aldosterone exists as an 11-18-hemiketal in solution and is not oxidized by this enzyme; therefore, it can exert its actions selectively in these target cells. Cells that do not contain the enzyme but do have MRs bind all three steroids; however, cortisol and corticosterone circulate in higher concentrations and gain entry to the brain much more easily than aldosterone; therefore, these steroids primarily occupy MRs in the brain. In the brain, MRs have a highly discrete distribution, primarily in neurons in entorhinal cortex, limbic structures, and motor output neurons. There is a very low density of MRs in the neurons of the hypothalamus.

2. The GR is a lower-affinity (K_d 10–30 nM) corticosteroid receptor that prefers dexamethasone $\gg$ cortisol, corticosterone $>$ aldosterone. The GRs are

distributed in every cell type in the organism. The distribution of GR in the brain is very widespread in both glial cells and neurons. CRH neurons in hypothalamus are well endowed with GRs, as are the neurons in the limbic system, the monoaminergic systems, and others.

Both occupied MRs and GRs dimerize in the cell nucleus to alter transcriptional rates of tissue-specific genes. In addition, MRs and GRs in the same cell can heterodimerize and act transcriptionally. Moreover, it is increasingly clear that the hormone receptor complexes can function in protein–protein interactions with other transcription factors to alter transcription rates. At this time, the specific effect of occupancy of MRs and GRs on transcription is impossible to predict. Nonetheless, occupancy of MRs and GRs by cortisol or corticosterone serves to inhibit activity in the HPA axis, generally by an action on brain.

Feedback regulation in the animal and its utility Using adrenalectomy and infusion of MR and GR agonists as well as treatment with specific antagonists in intact animals, it is clear that occupancy of the MRs is required to maintain ACTH secretion at low levels during the trough of the circadian rhythm. By contrast, at the circadian peak and during stress, the occupancy of both MR and GR restrains ACTH secretion, maintaining it within the normal limits observed in intact organisms. Because occupied GRs and MRs are powerful modulators of cell function, it is important to maintain their overall concentrations at

tightly regulated levels. Many corticosteroid-sensitive end points change their levels and activity when there is slight deviance on either side of the normal daily mean value. In studies of the daily mean of plasma cortisol in humans, values range from 6 to 8 $\mu\text{g dl}^{-1}$ when levels collected over 24 h are averaged. Similarly, in rats, the 24-h mean corticosterone concentration ranges between 4.5 and 7 $\mu\text{g dl}^{-1}$. Both species have relatively high circulating CBG levels. Above or below these ranges in unstressed humans and rats, untoward metabolic, behavioral, and immunological changes occur.

Temporally Discrete Effects of Corticosteroids on Hypothalamic-Pituitary-Adrenal Axis Function

Feedback inhibition of (CRH, AVP, and) ACTH secretion can be shown to exist in fast, intermediate, and slow time domains when corticosteroids are administered exogenously. Normally these segue smoothly from one to the other, but they can be distinguished mechanistically, and the degree of inhibition increases as the duration and amount of the corticosteroid exposure increases. In all time domains, the magnitude of the effect is strictly proportional to the dose of steroid, between the limits of threshold and saturating quantities.

1. The fast effects occur within milliseconds on neurons and must be exerted by an effect at the cell membrane. A membrane receptor has not yet been characterized. The iontophoresis of corticosteroids onto neurons or bathing tissue slices with corticosteroids shows effects within milliseconds to seconds on membrane function. Similarly, in animals the stimulation of pathways to CRH neurons does not evoke the normal response within minutes of a systemic injection of corticosteroids. At the pituitary corticotroph, CRH-stimulated ACTH secretion is inhibited within a few minutes of the application of corticosteroids; this inhibition is not altered by the inhibition of RNA or protein synthesis, showing that it is not mediated by the usual genomic effects of corticosteroids, although it may be mediated by interference with the generation of adenylyl cyclase, the intracellular messenger for CRH. The magnitude of the fast inhibition of ACTH secretion by corticosteroids acting on the corticotroph is small ($\sim 25\%$ of the maximal inhibition possible); thus, fast feedback leaves the organism responsive to further stressors and capable of secreting nearly normal amounts of ACTH.

2. Intermediate feedback has its onset at approximately 30 min after a pulse or continuous exposure to the steroid and lasts for a period of hours. The inhibition of protein synthesis with cyclohexamide blocks this feedback and, although it is powerful and can

completely inhibit CRH-induced ACTH secretion in the whole animal, ACTH secretion can usually be stimulated by further treatment with CRH or AVP. This temporal domain of corticosteroid feedback appears to dampen the excitability in the HPA axis without abolishing it (i.e., excitability is returned to prestress levels so that subsequent responsivity is not excessive). At the pituitary, AVP-stimulated ACTH secretion is less sensitive than CRH to corticosteroid inhibition.

3. Slow feedback is found in conditions in which the supraphysiological levels of exogenous corticosteroids have been provided for days or weeks. All components of the HPA axis are unresponsive to stimulation, both by intense stressors and, at the pituitary, by CRH and AVP. The CRH and AVP mRNA expression in the hypothalamus and proopiomelanocortin expression in the pituitary is markedly decreased. This condition is most frequently observed in humans with active Cushing disease or after prolonged treatment of disease with high levels of synthetic glucocorticoids; it takes months to recover from this inhibition when the high levels of steroid are removed.

Conditional Feedback in the Hypothalamic-Pituitary-Adrenal Axis

Up to this point, glucocorticoid feedback properties have been discussed with respect to the normal unstressed organism. Under conditions of persistent or chronic stress, the axis appears to change, and sensitivity to the feedback action of corticosteroids is slightly to markedly reduced. Thus, under chronic stress, mean daily plasma corticosteroid concentrations increase, frequently only because circadian trough levels are elevated but occasionally because there are major stressor-induced elevations throughout the circadian cycle. With chronic stress, the degree of the inhibition of stimulated ACTH secretion by exogenous (or endogenously secreted) glucocorticoids is decreased. In rats, chronic stress often stimulates increased expression of AVP in CRH-synthesizing neurons, thus providing a means for amplifying the corticotroph response to the CRH and AVP secreted. However, it also appears that neural sites upstream from the final hypothalamic CRH and AVP motor neurons of the HPA axis are less sensitive to corticosteroid feedback.

A decreased number of GRs has been reported, primarily in hippocampus, after many chronic stressors and after treatment with exogenous glucocorticoids, suggesting that one mechanism of reduced feedback sensitivity may reside in GR downregulation. This is not the only explanation for reduced feedback sensitivity during chronic stress, however, because there are several examples in which both MR and GR

numbers are normal throughout brain but glucocorticoid feedback insensitivity is found.

Because the strength of inputs to the CRH and AVP cells stimulates dose-related output, it is likely that, although corticosteroid dose-related functions are occurring normally under chronic stress conditions, the level of input to the CRH and AVP cells increases. Thus, normal responsivity in the HPA axis is maintained, whereas the apparent feedback efficacy of glucocorticoids is reduced. It does appear that new stimuli presented to chronically stressed animals causes facilitated responses in the central neural pathways to the CRH and AVP neurons.

The result of the apparent decrease in glucocorticoid feedback under conditions of chronic stimulation of the HPA axis is that there is dampening of the response to the ongoing stimulus but full or even exaggerated responsiveness to a new and different stimulus. Both effects are useful – the degree of hyperglucocorticoidism is limited by ongoing glucocorticoid feedback, but the organism is still capable of responding to a new stimulus that may demand a momentary shot of the hormones for optimal response.

Site(s) of Negative Feedback in the Hypothalamic-Pituitary-Adrenocortical Axis

Feedback is primarily exerted in the brain under normal conditions, with only moderate increases in mean corticosteroid levels or low-magnitude acute stressors. Although the CRH and AVP neurons in the PVN are plentifully supplied with GRs, this site does not appear to be inhibited directly by the naturally occurring corticosteroids. Instead, the corticosteroids appear to inhibit the activity of neuronal pathways that eventually impinge on CRH and AVP neurons. At high sustained corticosteroid levels, there is also clearly negative feedback on anterior pituitary corticotrophs.

Feedback in the Brain

Microinfusions of low amounts of MR and GR antagonists into the cerebral ventricles or into specific brain sites augment the magnitude of ACTH responses to a variety of stressors, strongly suggesting that stress-induced glucocorticoid secretion decreases the stimulatory input to the PVN during both the fast- and intermediate-feedback time domains. Small crystalline implants of corticosterone placed chronically into prefrontal cortex, the preoptic area, and the dorsal hippocampus have been shown to reduce stress or adrenalectomy-induced ACTH secretion. However, it appears that steroids implanted into brain must bathe those neurons that are activated by

the specific stressor used to excite the HPA axis. That is, there appear to be distributed sites at which steroids may inhibit HPA responses to stressors, not a single feedback site that globally inhibits PVN neuronal responses to stressors. Corticosteroids, acting through both MRs and GRs, have been shown to alter neuronal properties and activity in the hippocampus, and antagonists infused into both the amygdala and hippocampus have been shown to alter conditioned behaviors. However, it has not yet been directly demonstrated that implants in these sites alter the amount of ACTH secreted in response to a stressor. It may well be that corticosteroid receptors in these sites have little to do with modulating CRH and AVP secretion directly. In the brain, it appears that for feedback effects of steroid implants to be observed on ACTH secretion the steroid must act on sites that are also activated by stress; the feedback action is selective and specific.

Feedback at the Pituitary

Corticotrophs contain GRs but not MRs, and the direct inhibitory effects of corticosteroids are evident at the anterior pituitary. The concentrations of the naturally occurring steroids required to effect the inhibition of ACTH secretion are relatively high. This is probably because corticotrophs contain the high-affinity CBG corticosteroid binder apparently taken up from the circulation. The CBG in the corticotrophs sequesters the natural corticosteroids and high concentrations (10^{-8} M) are required to observe inhibition, although dexamethasone, which does not bind to CBG, is a more effective inhibitory agent. Moreover, corticotrophs tend to maintain sensitivity to AVP, although sensitivity to CRH decreases when corticosteroid levels are elevated. The relative insensitivity of the corticotroph to corticosteroid inhibition is useful because it allows the corticotroph to be the site of last resort, requiring the highest levels of signal, for the global inhibitory control of the HPA axis.

Glossary

<i>Corticosteroids</i>	Hormones synthesized in the adrenal glands, secreted in a circadian rhythm and in response to stress. The main endogenous glucocorticoids are corticosterone in rodents and cortisol in humans.
<i>Corticosteroid receptors</i>	Intracellular receptor molecules for corticosteroid hormones. On hormone binding they function as transcription factors in the nucleus of the cell to regulate the expression of target genes. There are two types: mineralocorticoid receptors and glucocorticoid receptors.
<i>Depression</i>	Psychiatric disorder characterized by core symptoms such as depressed mood, anhedonia, and loss of interests. The syndrome also includes changes in cognition, psychomotor alterations, and vegetative symptoms (changes in sleeping, eating, and sexual behaviors).
<i>Hypothalamic-pituitary-adrenocortical (HPA) axis</i>	The brain-controlled activation pathway for the secretion of corticosteroid hormones after stress through a hormonal signaling cascade, involving release of

Learned helplessness

Stress

Transgenic mice

corticotropin-releasing hormone from the paraventricular nucleus of the hypothalamus in the brain and adrenocorticotrophic hormone from the pituitary gland.

A psychobiological concept that predicts that stressors are particularly apt to induce depressive states when they are unpredictable and uncontrollable.

A physiological and psychological state caused by a real or perceived challenge to homeostasis, which is accompanied by a hormonal stress response.

Animals with a gene knockout (loss of function) or a transgene expressing an additional gene product (gain of function), designed by targeted mutagenesis. With modern techniques, genes can be overexpressed or shut down in a brain regional or temporal-specific way.

Corticosteroids, Corticosteroid Receptors, and Depression

Dysregulations and dysfunctions of corticosteroid receptors have been implicated in the pathogenesis of stress-related psychiatric disorders such as depression and posttraumatic stress disorder. It is still unclear, however, whether these corticosteroid receptor disturbances are a cause or a consequence of affective disorders. Clinical studies have demonstrated a hyperactivity of the hypothalamic-pituitary-adrenocortical (HPA) system with elevated plasma cortisol levels in many patients with major depression. In these patients, diminished corticosteroid receptor expression or function has been postulated as a causative

factor for a deficient feedback of cortisol that may explain their increased HPA activity and stress sensitivity. An alternative hypothesis claims that the primary cause of the HPA dysregulation is an up-regulation of hypothalamic corticotropin-releasing hormone (CRH) levels, which secondarily leads to corticosteroid receptor downregulation in the limbic system and the hypothalamus that perpetuates the disease state. According to the latter concept, the changes of the HPA system may result from a primary disturbance of monoaminergic systems and their widespread connections to higher brain centers, including cortex, limbic system, and hypothalamus.

Corticosteroids exert their effects via two types of receptors: high-affinity receptors for cortisol called mineralocorticoid receptors (MRs) because of their ability to bind also mineralocorticoids (e.g., aldosterone), and low-affinity receptors called glucocorticoid receptors (GRs), which mainly bind cortisol or corticosterone. MRs are predominantly found in the limbic system, in particular in the hippocampus, whereas GRs are ubiquitously expressed throughout the central nervous system. Functionally, MRs are thought to be involved in the physiological maintenance of the HPA system, while GRs are supposed to control the recovery from stress. Corticosteroid receptors are intracellular proteins and function as transcription factors. Their ligands are lipophilic and can easily cross the cytoplasmic membrane. Inside the cell, activation of the receptors provokes their translocation to the nucleus, where they bind to specific sequences on the DNA (glucocorticoid response elements [GREs]) and enhance or repress the transcription rate of their target genes. GRs can also up- or downregulate gene transcription by direct interaction with other transcription factors such as CREB or AP-1.

Activation of corticosteroid receptors in neurons can influence diverse cellular processes such as energy metabolism, signal transduction, and even structural plasticity. Functional consequences include the control of excitability in limbic brain regions, in particular in the hippocampus. The corticosteroid receptor-mediated effects at the cellular level have consequences for processes in which the hippocampal formation plays an essential role, e.g., in the neuroendocrine regulation of the HPA system and also in behavior. Thus, apart from emotional behavior, corticosteroids also influence perception as well as learning and memory.

According to current concepts, GR-mediated functions in particular are disturbed in patients with severe depressive episodes. However, since studies of the GR in the human brain are not feasible *in vivo*, such evidence is mostly derived from pharmacological

challenge tests, such as the dexamethasone suppression test, which indirectly measures GR function in the pituitary and maybe in part also in the central nervous system. Thus, the analysis of direct effects of GR dysfunction and its potential role in emotional behavior is restricted to animal models. For this purpose, targeted mutagenesis in mice seems to be particularly promising.

Animal Models of Depression

Good animal models of human depression should fulfill the following criteria as best as possible: strong behavioral similarities (e.g., similar core symptoms), common etiology, similar pathophysiology, and common treatment. Such a model could then be used to elucidate molecular and biochemical mechanisms underlying the pathogenesis of depression. One of the core symptoms of severe depression in humans and mice is anhedonia, i.e., the lack of interest in pleasurable activities. In mice, anhedonia can be measured by a loss of preference for sweet solutions over tap water. Another core symptom is coping deficits in aversive but avoidable life situations. Confusion between a model and a test should be avoided. A model can be defined as an organism or a particular state of an organism that reproduces aspects of human pathology, providing a certain degree of predictive validity. A test is an end-point behavioral or physiological measure designed to assess the effect of a pharmacological or environmental manipulation. In this respect, models of depression are different from the tests used to monitor the effects of antidepressants. Behavioral despair paradigms such as the Porsolt forced swim test and the tail suspension test cannot be considered models of depression, even though their efficiency to screen for antidepressant-like activity is widely accepted. Nevertheless, increased despair behavior in these tests can be regarded as part of a depressive syndrome.

Two paradigms induce anhedonia in mice: the chronic mild stress model and the learned helplessness paradigm. In the chronic mild stress model, animals are subjected for several weeks to a series of mild stressors (intermittent food and water deprivation, overnight illumination, cage tilt, noise, etc.). This treatment induces a reduction of sucrose preference, decreased intracranial self-stimulation, altered sexual and aggressive behavior, loss of body weight, sleep disturbances, and overactivation of the HPA system. These symptoms are reversible upon administration of antidepressants. In the learned helplessness paradigm, animals are exposed to inescapable electric footshocks, which induce a number of deficits similar to those observed after chronic stress: failure in avoidance learning, lower preference for sucrose solution, decreased appetite, loss

of body weight, and overactivation of the HPA system. Again, these effects are reversed by the administration of antidepressants. Thus, the behavioral and somatic deficits observed in these two models mimic the human depressive syndrome.

A major drawback of the previous models is the difficulty of knowing whether the pathological changes observed are due to the animals' depressive state or rather reflect the manipulation by which this state was induced, e.g., stress or pharmacological treatment. An alternative animal model of affective disorders would be an endogenous, genetic model, independent of external factors, which mimics essential aspects of the human disorder and responds to standard regimens of therapy. Mouse mutants with altered HPA system activity are candidate strains for a murine depression-like syndrome, because HPA system imbalances are a key biological marker for a major depression in humans. In particular, alterations of corticosteroid receptors appear promising in modeling affective disorders. Different strains of mutant mice have been or can be obtained with over- or underexpression of glucocorticoid receptors. Current techniques even allow a conditional gene disruption in specific brain regions, in the best case inducible at a selective time point.

Mice with Targeted Mutations of GR

Several mouse strains with altered GR expression or function have been generated (Table 1). The mice produced earlier (before 2000) did not exhibit a behavioral depression-like phenotype. Thus, mice with a GR point mutation (GR^{dim}) that prevents GR dimerization and binding to its cognate element GRE have not revealed any changes in emotional behavior. Surprisingly, a GR antisense model with reduced expression in the brain as well as a strain with a

brain-specific GR knockout (GR^{NesCre}) exhibited reduced depression-like behaviors. However, these paradoxical findings may be explained by the fact that a complete lack of GR prevents all stress- or corticosterone-induced effects usually mediated by GRs and results in a stress-resistant phenotype. With respect to human genetics and psychopathology, the genetic defects generated in these early mouse strains are very unlikely to occur in humans.

To mimic certain quantitative or functional alterations of GRs – as postulated for depressive patients – mice were generated that have either a 50% reduced or a twofold increased GR gene dosage (Figures 1 and 2). Moreover, in these mice the genetic context controlling the GR gene was preserved as much as possible to maintain the regulatory principles governing the normal gene. Such mice have been generated by homologous recombination (GR^{+/-} mice) and by a transgenic approach (YGR mice). The latter strain contains two additional copies of the GR gene. This strain was generated by transfer of a yeast artificial chromosome of 290 kb in length, providing the transgenes with the natural chromosomal context of the mouse genome, resulting in expression of the GR transgenes in a copy number-dependent and position-independent manner. According to the molecular hypotheses of depression, one would expect that mice with reduced expression levels of GR (GR^{+/-}) have a predisposition to develop depression-like behavior. Current hypotheses would also predict that mice overexpressing GR (YGR) are more resistant to developing depression-like features than wild-type mice. To test these hypotheses, GR^{+/-} and YGR mice were subjected to a standardized battery of tests for emotional behavior, including tests for depression-like signs such as despair and helplessness. Furthermore, the HPA system was analyzed under baseline conditions, after stress, and following a Dex/CRH challenge. Moreover, the content of brain-derived neurotrophic factor (BDNF) was determined in the hippocampus, since BDNF has been postulated to play a critical role in pathogenesis and therapy of affective disorders.

GR^{+/-} Mice Exhibit a Depression-like Behavioral and Neuroendocrinological Phenotype

GR^{+/-} mice did not exhibit phenotypical changes under basal conditions in a test battery for locomotor, exploratory, anxiety-related, and emotional behaviors. In this context, it is of interest that a selective loss of GR function in hepatocytes did not affect gluconeogenesis under basal conditions, but caused a gluconeogenesis deficit under challenge conditions by fasting the animals. Similarly, GR^{+/-} mice exhibited a depression-like phenotype, i.e., increased

GR ^{+/-} mice	Ridder et al. (2005)

Figure 1 Genetic manipulation. The GR null allele was obtained by deleting the third exon (and a subsequent frame shift), leading to a truncated GR protein without functional domains. Heterozygous mice that underexpress GR exhibit normal baseline behaviors, but after stress exposure they demonstrate significantly increased learned helplessness. Similar to depressed patients, they show a disinhibition of the HPA system and a pathological Dex/CRH test. In agreement with the neurotrophin hypothesis of depression, they have reduced BDNF levels in the hippocampus. Thus, these mice represent a strain with a predisposition to develop depression-like features after stress.

helplessness, after being challenged by environmental stress (Figure 1). The learned helplessness model is a rodent depression model with good face and construct validity. It is based on the concept that depressed individuals show a loss of coping strategies in aversive environmental situations. GR^{+/-} mice demonstrated significantly prolonged escape latencies and increased failures in the active avoidance task of the learned helplessness paradigm after two sessions of footshock exposure. The impaired coping behavior strongly indicated the development of depression-like behavior in GR^{+/-} mice.

This altered behavioral reactivity to stress was accompanied by depression-like alterations of the

HPA system. Similar to the behavioral level, changes of the HPA axis were not present under basal conditions in GR^{+/-} mice, but a significant disinhibition occurred after stress. Furthermore, GR^{+/-} mice exhibited a pathological Dex/CRH test, currently the most relevant biological marker in patients for both florid depression and the risk of developing a depressive episode. This test combines the suppressive effect of dexamethasone with the stimulatory potency of CRH. In 70–80% of severely depressed patients the CRH-elicited adrenocorticotrophic hormone (ACTH) and cortisol response is blunted, and dexamethasone pretreatment does not elicit a suppressive effect and paradoxically induces enhanced cortisol levels

Figure 2 Genetic manipulation. YGR mice were generated by introducing two copies of the GR gene into the mouse genome with the help of the yeast artificial chromosome (YAC), which contains the entire GR locus of 110 kb with all regulatory sequences. Transgenic mice that overexpress GR in the brain are less sensitive to stress. Following immobilization, their HPA system returns to homeostasis faster than in wild-type. Behaviorally, they demonstrate better coping when exposed to stress than control littermates, even though baseline behavior is unaltered. Therefore, these mice represent a depression-resistant strain.

following a CRH challenge. In healthy individuals, in contrast, the Dex/CRH test creates the situation of a pharmacological (partial and transient) adrenalectomy in which hypothalamic CRH expression is increased due to a decrease in plasma cortisol. Similarly to depressed patients, GR^{+/-} mice display a characteristic nonsuppression following dexamethasone treatment and the paradoxical increase of corticosterone levels after combined Dex/CRH application.

Normal Baseline Behavior and Neuroendocrinology of GR^{+/-} Mice May Reflect Developmental Compensation

Using modern transgenic techniques, recently a mouse strain was generated with a forebrain-specific

complete GR knockout, induced by the calcium-calmodulin-dependent protein kinase II (CamKII) promoter. In contrast to GR^{+/-} mice, these mice exhibited at 3 weeks of age a depression-like phenotype under basal (unstressed) conditions. This indicated that GR underexpression from early development on does not lead to an overt phenotype under baseline conditions with low levels of stress. This could be due to a mere gene dosage effect. Furthermore, a complete GR knockout in some brain areas with preserved GR levels in other regions may have resulted in a different phenotype than a more subtle and homogenous GR reduction throughout the brain. However, the depressive phenotype of forebrain-specific GR knockout mice also indicated that crucial

brain regions responsible for the phenotype of GR^{+/-} mice may be located in the forebrain. On the other hand, the lack of a phenotype under baseline conditions of GR^{+/-} mice might also be caused by early ontogenetic compensatory or adaptive processes, possibly reflecting the condition of patients with a high genetic (familial) risk for depression who are initially inconspicuous but develop depressive episodes following stressful life events.

Since depression is a multifactorial disease, the moderate dysregulation of a single system may not be sufficient to induce depression-like alterations in mice under basal conditions. Therefore, provoking or destabilizing factors, such as stress or early childhood environmental factors, may be needed in addition to the existing genetic predisposition to effectively elicit a behavioral and also a neuroendocrinological phenotype. This concept may explain why the depression-like phenotype of GR^{+/-} mice manifests only after stress. The latter fact, however, can be regarded as a strength of the heterozygous model, because depression-vulnerable humans often develop a depressive episode only following external or internal stress factors.

YGR Mice Overexpressing GR Are Stress Resistant

A genetic approach to prove the specificity of the depression-like alterations of GR^{+/-} mice seemed to be the behavioral and neuroendocrinological examination of mice overexpressing GR. In these mice one would expect the opposite phenotype of GR^{+/-} mice. Indeed, YGR mice carrying four copies of the GR gene demonstrate a stress resistance on both the behavioral and the hormonal level. These animals exhibit less helplessness, lower corticosterone levels after stress, and oversuppression following dexamethasone treatment (Figure 2). This result was in good agreement with the predictions of the GR hypothesis of depression.

Recently it was also reported that mice overexpressing GR specifically in the forebrain displayed increased emotional lability in the Porsolt forced swim test, indicated by increased baseline immobility. Furthermore, these animals exhibited increased anxiety-like behavior in the elevated plus-maze and in the dark-light box. This was not observed in the YGR mice that express GR under control of its own regulatory sequences. These contradictory results could be explained by the late onset and forebrain restricted mutation induced by CamKII promoter used in the former study. Conflicting results also come from the human field. While enhanced glucocorticoid feedback has always been considered positive for better limiting the stress response, it is important to remember that overactive GR may transduce a stronger

glucocorticoid signal, i.e., it may produce effects of glucocorticoid excess. In a large elderly Dutch (Rotterdam) population cohort, two different polymorphisms in GR have been found, one that enhances sensitivity to dexamethasone and the other that confers resistance to dexamethasone. However, the group with increased sensitivity to dexamethasone (and lower basal cortisol) shows a glucocorticoid excess phenotype with greater incidence of dementia and reduced overall survival. Thus, our understanding of the animal models needs to examine additional possibilities of what reduced or increased glucocorticoid signaling entails beyond HPA feedback or learned helplessness models.

GR Mutant Mice Represent a Tool to Study Molecular Correlates of Depression-like Behavior

The results in GR^{+/-} mice resemble the human situation in depressive disorders, in which individuals at risk are predisposed to develop depressive episodes after stress. In this respect, GR^{+/-} mice differ from mice with a forebrain-specific complete GR knockout, which already demonstrate depression-like behavioral and neurochemical alterations under baseline conditions. However, the findings in both strains indicate that compromised GR function constitutes a crucial molecular risk factor in the pathophysiology of depression. This suggests that the mouse lines with altered GR expression are suitable tools for further physiological, biochemical, and pharmacological investigations of GR function with regard to depressive disorders. These analyses are also of clinical relevance, since in preliminary studies GR antagonists have been of value in the treatment of severe depressive episodes with psychotic features.

Recently, the so-called neurotrophin hypothesis of depression postulated that a downregulation of brain-derived neurotrophic factor (BDNF) is crucial for the pathogenesis of depression in humans and rodents. A stress- or corticosterone-induced BDNF downregulation in the hippocampus can be partially blocked by adrenalectomy or can be reversed by antidepressant therapy. In accordance with this hypothesis, GR^{+/-} mice – which have a predisposition to stress-induced depression-like behavior – show a significant downregulation of BDNF in the hippocampus, while YGR mice exhibit a significant BDNF upregulation. Indeed, this was the first experimental evidence that compromised GR function concurrently evokes a BDNF dysregulation and a predisposition to depressive behavior. Future experiments should investigate in these strains further mechanisms of neural plasticity thought to be involved in the molecular and

cellular pathogenesis of depression, e.g., monoaminergic systems, arginine vasopressin, and neurogenesis. Using modern molecular techniques such as transcriptomics and proteomics, completely new or even unknown gene products that are involved in the pathogenesis of depression may be detected. Such gene products may represent new targets for antidepressive treatment and could help to develop therapeutic strategies that are faster and more efficient than those currently in use.

Glucocorticoid Receptor Mutations
Glucocorticoid Receptor Polymorphisms

Glossary

<i>Mutation</i>	Changes to the genetic material.
<i>Polymorphism</i>	The occurrence in the same habitat (DNA sequence) of two or more forms of a trait in such frequencies (usually >1%) that the rarer cannot be maintained by recurrent mutation alone.
<i>SNP</i>	A DNA sequence variation, occurring when a single nucleotide: A, T, C, or G – in the genome differs between members of the species.

Glucocorticoid Receptor Mutations

Some abnormalities in glucocorticoid (GC) response may be explained by mutations in the gene coding for the GC receptor (GR; NR3C1). Such mutations can occur either in the germline, causing systemic GC resistance or hypersensitivity, or they can occur somatically, resulting in localized changes in GC sensitivity, e.g., in tumors.

Germline Mutations, Glucocorticoid Resistance, and Glucocorticoid Hypersensitivity

Based on the results of experiments with knockout mice, it is clear that total absence of the GR is not compatible with life, and the germline mutations that have been identified in the GR gene have always been found to confer a relative GC resistance, which was compensated by increased activity of the hypothalamic-pituitary-adrenal (HPA) axis. Typically, the symptoms of most patients could be explained by the concurrent overproduction of adrenal androgens (hirsutism, fertility problems in women, male precocious puberty in a boy) and mineralocorticoids (hypokalemia, hypertension).

Worldwide, nine different cases of GC resistance caused by mutations in the GR gene have been described (Table 1). Seven of these nine mutations are located in the ligand-binding domain and resulted in reduced ligand affinity. One mutation resulted in the

(heterozygous) destruction of a splice site, and hence in a reduced amount of GR messenger ribonucleic acid (mRNA) and GR protein per cell. One mutation was located in the deoxyribonucleic acid (DNA)-binding domain and resulted in the ablation of trans-activating capacity. The low number of cases of GR-gene mutations stands in strong contrast to the situation with respect to the androgen receptor, where in patients with the partial- or complete androgen insensitivity syndromes hundreds of different mutations have been identified. Several explanations for this are possible: (1) the GR is more essential to (prenatal) survival than the androgen receptor, resulting in the occurrence of relatively mild mutations only, (2) the symptoms of GC resistance are relatively mild, resulting in an underestimation of the number of cases.

Several cases of GC hypersensitivity (typically, the presence of the symptoms of Cushing's syndrome combined with low serum cortisol levels) have been described; however, none of these have been explained by the presence of mutations in the GR gene. Due to the extremely low number of cases there are no data available on the effects of this type of mutations on the stress response.

Somatic Mutations in Tumors and Tumor Cell Lines

GCs play an important role in the treatment of a number of hematological malignancies and lack of response to this treatment might be associated with mutations in the GR gene. However, in the current literature only very limited numbers of such mutations has been reported. Similarly, involvement of GR-gene mutations in adrenocorticotrophic hormone

(ACTH)-secreting pituitary adenomas has been shown in only a small number of studies.

Glucocorticoid Receptor Polymorphisms

The National Center for Biotechnology Information (NCBI) single nucleotide polymorphism database currently shows 461 SNPs in the human GR gene. Most of these are in noncoding sequences of the gene and have not (yet) been investigated with respect to functionality. Five SNPs in the GR gene have been investigated more extensively (Table 2). The main effects that have been observed for these polymorphisms are on body composition and metabolic profile (fat mass, fat distribution, lean mass, and serum lipids), but two polymorphisms have also been associated with changes in the response to psychosocial stress. Carriers of the N363S polymorphism showed an increased HPA-axis response when challenged with the Trier Social Stress Test, while carriers of the Bcl-I polymorphism showed a reduced response.

In general it can be said that the effects of these polymorphisms are relatively small. They can barely be measured in individuals, and their effects have been suggested to be due to lifelong exposure to small changes in GC sensitivity, rather than to changes in the acute HPA response.

Background

GCs and the Function and Structure of Hippocampal Neurons

GCs and the Birth of Hippocampal Neurons

GCs and the Death of Hippocampal Neurons

GCs and the Health of the Human Hippocampus

Glossary

Dendritic atrophy The shrinking of the dendritic processes by which neurons receive excitatory or inhibitory inputs from neighboring neurons.

Glucocorticoids Steroid hormones released by the adrenal gland basally and in response to virtually all stressors.

Hippocampus A region of the brain that plays a central role in learning and memory and in the

regulation of the adrenocortical axis; it is atypically vulnerable to a number of neurological diseases and has an atypically high concentration of receptors for glucocorticoids.

Neuron death The death of brain cells that can be due to disease or as part of normal development (i.e., programmed cell death).

It has long been appreciated that prolonged stress or exposure to glucocorticoids (GCs) can have adverse effects throughout the body. In recent decades, it has become clear that these adverse effects can extend to the nervous system, particularly the hippocampus, a brain region critical to learning and memory and with an abundance of corticosteroid receptors. These effects of GCs and stress include (1) reversible atrophy of dendritic processes, (2) inhibition of neurogenesis in the adult hippocampus, (3) compromising of the ability to neurons to survive a variety of insults, and (4) overt neurotoxicity. This article considers the emerging insights as to the cellular and molecular mechanisms underlying these events, as well as the possible clinical implications (including in the realm of normative aging, treatment with exogenous GCs,

Cushing's disease, posttraumatic stress disorder, and depression).

Since the time of Walter Cannon, there has been recognition of the critical role of the stress response in maintaining allostatic balance in the face of insult and injury. However, since the time of Hans Selye, there has been the complementary recognition that excessive activation of the stress response can be deleterious, increasing the likelihood of a disease occurring or exacerbating some preexisting disease. The pages of this encyclopedia are filled with ample documentation of the adverse effects of overactivation of the stress response on metabolism, cardiovascular function, reproductive physiology, and so on, and these realms represent the cornerstones of stress pathophysiology. Only more recently has it become clear that excessive activation of the stress response can have deleterious effects on the nervous system.

Background

An array of physiological and psychological stressors causes secretion of catecholamines by the sympathetic nervous system and of glucocorticoids (GCs) by the adrenal cortex. While such peripheral catecholamines do not pass the blood–brain barrier, the steroidal GCs do so readily and appear to be the culprits in damaging the nervous system.

The deleterious effects of GC excess within the nervous system are centered in (but not exclusive to) the hippocampus, the limbic structure that plays a central role in learning and memory. The first hints of such deleterious actions came at a time when it was not yet obvious why the hippocampus should be particularly sensitive to GCs and thus were mostly ignored. This changed in the late 1960s, with the classic work of Bruce McEwen and colleagues, who demonstrated the extremely high levels of receptors for GCs (i.e., corticosteroid receptors) in the hippocampus. Since then, vast numbers of studies have documented the extensive neurochemical and electrophysiological sensitivity of the hippocampus to GCs, and it is basically impossible to think of stress, GCs, and the nervous system without thinking first about the hippocampus.

In the mid-1980s, E. Ron de Kloet and colleagues made the critical observation that there are two types of corticosteroid receptors in the nervous system, with the hippocampus having ample amounts of both. These are the high-affinity, low-capacity mineralocorticoid receptor (MR), and the low-affinity, high-capacity glucocorticoid receptor (GR). The existence of these two receptors, and their possessing such different affinities, clarify a key feature of GC action in the hippocampus. Specifically, mild

elevations of GCs, or mild transient stressors, enhance hippocampal-dependent cognition, as well as the synaptic plasticity that mediates such cognition (such long term potentiation [LTP]); this makes sense, in that mild, transient stressors are what we think of as stimulation, something that very much enhances cognition. In contrast, major and/or prolonged stressors or GC exposure has opposite, disruptive effects on cognition. This U-shaped curve of GC effects on hippocampal function (a concept popularized by David Diamond) was explained by the two-receptor system in the hippocampus. Specifically, the high-affinity MRs are mostly occupied basally and are then fully occupied by mild elevation of GC concentrations. Such MRs mediate the salutary effects of GCs upon cognition (i.e., the permissive effects of GCs basally, and the enhancing effects of mild stressors). In contrast, GRs, which are minimally occupied basally and are not heavily occupied until there is a major stressor, mediate the disruptive effects.

GCs and the Function and Structure of Hippocampal Neurons

As just discussed, mild stressors, via MR occupancy, enhance hippocampal-dependent cognition and LTP, whereas major stressors, via GR occupancy, disrupt both. The mechanisms underlying these actions are well understood.

Major stressors and prolonged GC exposure can also cause structural changes in hippocampal neurons. Neurons are highly arborized cells, with information flowing in from neighboring neurons via a dense tree of processes called dendrites, and with information flowing out through a major cable called the axon. The extent of dendritic arborization – the length and complexity of processes – is now recognized to be highly dynamic, being remodeled by a variety of local, systemic, and even experiential influences. Work initiated by McEwen and colleagues has shown that in the rat, sustained exposure to stress or to excessive GC levels over the course of weeks can cause atrophy of dendrites in hippocampal neurons. Reflecting the dynamic nature of dendritic remodeling, the atrophy appears to gradually reverse when the stress or GC overexposure stops. Subsequent work from this group and others has shown that the same atrophy occurs in the nonhuman primate hippocampus as well.

It is the GR receptor that appears to mediate the deleterious GC effects on the dendrites. Moreover, GCs appear to cause the atrophy through the glutamate neurotransmitter system. As evidence, atrophy can be prevented by blocking NMDA glutamate receptors in the hippocampus or by the use of drugs

that blunt glutamate release (such as the seizure suppressor phenytoin). Thus, the phenomena of GC-induced dendritic atrophy and of neuroendangerment appear to be linked mechanistically.

What are the consequences of this dendritic atrophy? There are at least three possibilities. First, part of the staggering complexity of the nervous system comes from the multiplicity of synaptic connections between neurons, and a typical neuron can form thousands of synapses with neighbors both near and far. The existence of such neuronal networks is obviously dependent upon an intact dendritic tree, and dendritic atrophy is likely to disrupt and simplify networks within the hippocampus. Stress or GC overexposure on the scale needed to cause dendritic atrophy will also disrupt cognition, and it seems plausible that the two are interrelated. Second, as will be reviewed shortly, GCs and stress can make hippocampal neurons less likely to survive coincident neurological insults. It has been suggested that the dendritic atrophy represents, in effect, a hibernation, of a neuron, an involution that protects it from a coincident insult. Third, in contrast, others have suggested that the atrophy represents a marker of the neuron being made more vulnerable, rather than less, to an insult. While it remains unclear whether the first two models are correct, most existing evidence supports the last.

GCs and the Birth of Hippocampal Neurons

For much of the twentieth century, a central dogma of neuroscience was that the adult mammalian brain did not make new neurons. The 1990s saw an overthrow of this view, with the recognition that a handful of generally ignored pioneering studies in the 1960s disproved this maxim, and the study of adult neurogenesis is now one of the most vibrant fields of neuroscience. Such neurogenesis occurs in only two regions of the brain (the hippocampus being one of them) and is stimulated by environmental enrichment, learning, voluntary exercise, and estrogen. An enormous amount of work has demonstrated that these are, indeed, neurons, that they can migrate some distance from their site of birth, and that they form functional synapses with preexisting neurons. Some of the current issues in the field include (1) whether such neurogenesis occurs in other brain regions as well (particularly the cortex); (2) how much neurogenesis occurs (with estimates ranging from rates that would completely replace certain hippocampal cell fields throughout the lifetime to rates that place the levels orders of magnitude lower); and (3) whether these new neurons are necessary for any

aspects of hippocampal function. These issues are quite contentious in this often fractious field.

One of the more consistent findings is that stress and GCs potently and rapidly (over the course of hours) inhibit adult hippocampal neurogenesis, a finding pioneered by Elizabeth Gould and colleagues. The mechanisms underlying this are unclear. As but one example, early reports suggested that neural progenitor cells in the adult hippocampus do not express MRs or GRs, and that the inhibitory effects of GCs had to be through neuron/progenitor interactions; more recent work, using more sensitive assays, suggests that progenitors do indeed possess GRs. Also unclear is how much the effects of GCs on neurogenesis contribute to any of the disruptive effects of GCs upon hippocampal function.

GCs and the Death of Hippocampal Neurons

GC Endangerment

A body of work initiated by Robert Sapolsky and colleagues in the 1980s demonstrated the ability of transient bursts of GC excess to endanger hippocampal neurons, compromising their ability to survive a coincident neurological insult. As such, the greater the GC levels at the time of an insult, the greater the extent of hippocampal damage. Such insults include epileptic seizures, hypoxia-ischemia, hypoglycemia and other metabolic insults, oxidative insults, the β -amyloid peptide (the fragment of the amyloid precursor protein that has been implicated in the neuron death of Alzheimer's disease), and gp120 (the coat protein of the AIDS virus that is thought to play a role in the neurodegeneration seen in AIDS-related dementia). This endangerment is of a considerable magnitude, with stress levels of GCs causing many-fold increases in insult-induced damage in some cases.

Features of this endangerment include the following: (1) it is mediated by GRs, rather than MRs; (2) while most dramatic in the hippocampus, the endangerment can also occur in the cortex and striatum; (3) it is a direct GC effect in the hippocampus (rather than secondary to some peripheral GC action), as the same phenomenon occurs in hippocampal cultures and tissue slices; and (4) it consists of GCs increasing the amount of insult-induced necrotic death, rather than an increase in the amount of apoptotic death (a form of programmed cell death).

In vitro models have made it possible to uncover some of the mechanisms underlying the endangerment. One realm concerns the disruptive effects of GCs upon neuronal energetics. GCs inhibit glucose transport in many peripheral tissues (as part of the

strategy to divert energy to exercising muscle during a stressful crisis); this effect is due to a reduction in the number of glucose transporter molecules in the cell membrane. GCs cause a similar inhibition in the hippocampus, leaving neurons energetically vulnerable, thereby worsening insult-induced declines in energy substrates (such as ATP). Such insults cause neurons to release damaging amounts of the excitatory neurotransmitter glutamate. This, in turn, causes a wave of calcium influx in the postsynaptic neuron, which causes an array of calcium-dependent degenerative events; of most significance is the generation of oxygen radicals. It is quite costly for a neuron to contain the excesses of glutamate, calcium, and oxygen radicals, and the mild energetic vulnerability caused by GCs makes each of these steps spiral a bit more out of control, increasing the likelihood of the neuron succumbing.

In addition to these energetic features, GC endangerment probably also arises from the demonstrated abilities of the hormone to increase calcium currents in hippocampal neurons, to decrease the activity of calcium-extrusion mechanisms, to suppress the levels or efficacy of neurotrophins (neuronal growth factors), and to disrupt some of the defenses normally mobilized by neurons during neurological insults.

At present, these data are derived exclusively from rodent and tissue culture studies. Should subsequent work demonstrate GC endangerment in the primate hippocampus, they have a number of disturbing implications. Numerous individuals are administered high-dose GCs to control autoimmune or inflammatory disorders, and this might well exacerbate the damaging effects of some neurological crisis. Plus, GCs are often administered after strokes in order to decrease brain edema (swelling). Most studies show that GCs are less effective at reducing such edema than nonsteroid anti-inflammatory compounds; the present studies suggest that the use of GCs might even worsen the neurological outcome. Finally, stroke, seizure, and cardiac arrest all cause massive GC secretion; such endogenous GC release might add to damage. In effect, what we have learned to view as the typical extent of neurological damage caused by these insults might well reflect the damaging effects of the maladaptive hypersecretion of GCs at that time.

GC Neurotoxicity

Independent of a coincident neurological insult, GCs can directly influence the life and death of a hippocampal neuron. In an unexpected finding, Robert Sloviter and colleagues reported that GCs are required for the survival of dentate gyrus neurons. In the complete absence of the hormone, such neurons undergo apoptosis within days, and

very low levels of GCs, via MR occupancy, prevent this effect.

A separate literature showed that truly prolonged exposure to elevated GC levels could directly kill hippocampal neurons. Studies initiated by Phil Landfield and colleagues showed that the loss was centered in the CA3 region of the hippocampus and was highly relevant to hippocampal aging. That region of the hippocampus loses neurons with age, and these studies suggested that it is the cumulative extent of GC exposure over the lifetime that acts as a major determinant of the extent of neuron loss (as well as of hippocampal-dependent memory problems) in old age. As such, stress has the capacity to accelerate hippocampal aging, whereas behavioral or social manipulations that reduce cumulative GC exposure can delay such aging. The finding of GC- and of stress-induced neurotoxicity was replicated by other investigators, including in the nonhuman primate hippocampus.

The mechanisms underlying such neurotoxicity are not well understood. The assumption by most in the field, however, is that it is on a continuum with GC neuroendangerment – in effect, if a day of GC overexposure can compromise the ability of a neuron to survive a massive neurological insult, months of overexposure can compromise its ability to survive the minor metabolic challenges of everyday life, especially during aging. The difficult studies required to test this idea remain to be carried out.

Despite the replication of the finding of GC neurotoxicity, the phenomenon is more controversial than the other adverse GC effects that have been discussed. The disagreements have focused on a number of issues. The basic finding of neuron loss during hippocampal aging has been called into question by some researchers counting neurons with the technique of stereology. Some investigators suggest that overt neurotoxicity can be caused only by massive amounts of ever-shifting stressors (to avoid habituation of the system) or by pharmacological GC exposure, questioning the relevance of the phenomenon to normative aging. GC hypersecretion and hippocampal neuron loss in old age are quite variable among rodents. There appear to be strains in which neither occurs to any dramatic extent. Moreover, dramatic differences in the extent of successful aging can occur within strains. Michael Meaney and colleagues, for example, have shown that remarkably subtle differences in the quality of early maternal care can change the entire trajectory of hippocampal and adrenocortical aging in a rat, in some cases completely avoiding the neuron loss or GC hypersecretion; thus, neither component of that cascade model is an inevitable part of aging. Finally, to the extent that

primates and humans hypersecrete GCs in old age, it is a nonlinear phenomenon, emerging only in extreme old age or when coincident with an insult (such as major depression or Alzheimer's disease).

GCs and the Health of the Human Hippocampus

Work in the past decade suggests that these findings regarding the deleterious effects of GCs and stress apply to the human hippocampus. These findings have been most striking in a number of realms.

Cushing's Syndrome

Cushing's syndrome can arise from any of a number of different types of tumors and results in vastly elevated levels of circulating GCs. Magnetic resonance imaging (MRI) studies by Monica Starkman and colleagues of Cushingoid patients have shown selective atrophy of the hippocampus. More strikingly, it is the same patients who have the most severe GC hypersecretion, the most severe hippocampal atrophy, and the most profound cognitive deficits. Post mortem studies to uncover whether this atrophy is due to neuronal loss, atrophy, or compression remain to be carried out. However, when the GC hypersecretion is corrected by removal of the tumor, the hippocampal gradually returns to normal size, in agreement with the model of reversible dendritic atrophy.

Exogenous GC Administration

Synthetic GCs are frequently administered in different realms of clinical medicine. Most cases involve transient exposure to fairly low concentrations, often through routes that do not result in much access of the steroids to the brain. However, there are hundreds of thousands of individuals on long-term, systemic high-dose GC treatment to control various autoimmune or inflammatory diseases. Difficult case-controlled work by Pamela Keenan and colleagues demonstrates that independent of the disease, treatment with such steroids increases hippocampal-dependent cognitive deficits. The mechanisms underlying this effect (e.g., whether it is due to dendritic atrophy, inhibition of neurogenesis, and so on) are unknown.

Clinical Depression

Major clinical depression is an archetypical example of a stress-related disease; as but three pieces of evidence, exogenous GC treatment increases the risk of depression, major stressors do as well, and about half of patients with major depression present with GC hypersecretion. Yvette Sheline and colleagues have

observed that a history of prolonged depression is associated with selective hippocampal atrophy on MRI. In this observation, since replicated, the more prolonged the depression, the more atrophy. While the necessary post mortem cell counting has not been carried out, the atrophy appears to be permanent in that it is demonstrable in individuals long after the depressions have resolved; whether this is due to loss of neurons or inhibition of neurons that would otherwise have been born is not clear. Some researchers have suggested a scenario of reverse causality, in which individuals who (for other unrelated reasons) have a smaller than average hippocampus are more at risk for clinical depression. However, such volume loss is not demonstrable shortly after diagnosis, and more prolonged depressions are associated with more volume loss; both findings argue against reverse causality.

Posttraumatic Stress Disorder (PTSD)

Probably the most contentious studies concerning GC effects on the human hippocampus concern PTSD. A large numbers of studies, with the first coming from J. Douglas Bremner and colleagues, demonstrate volume loss in the hippocampi of individuals with PTSD. Furthermore, the more volume loss, the more severe the cognitive impairments, and there is little evidence that either tends to reverse over time. The controversial issues are threefold.

First, are GCs the cause of the volume loss? This question is central to the second issue as well, but the first version of this question focuses on whether GC levels are elevated in PTSD. While it might seem intuitive that this is the case, many (but not all) studies suggest lower than normal levels and that such hyposecretion may even precede and predispose toward succumbing to PTSD. The studies showing hyposecretion, pioneered by Rachel Yehuda and colleagues, also suggest an enhanced sensitivity to GCs in these patients. This would then shift the issue from whether excessive GC levels play a role in the volume loss to whether excessive sensitivity to GCs plays a role.

The second controversy concerns when the volume loss occurs. There are three possibilities: (1) volume loss occurs in response to the trauma itself; (2) volume loss occurs in response to the biology of the prolonged posttraumatic period (i.e., the period of the PTSD); and (3) a small hippocampus (arising for reasons unrelated to stress or GCs) precedes and predisposes toward PTSD. This issue is not resolved, and, at present, there are some striking findings supporting, as well as arguing against, each of these possibilities. One reasonable solution is that from the

standpoint of hippocampal neurobiology, PTSD is a heterogeneous disorders, with all three occurring on occasion. Such heterogeneity is certainly seen in the clinical profile of the disorder.

The final issue is whether the volume loss is due to loss of neurons, blockage of birth of new neurons, atrophy of dendritic processes, loss of glia, and so on. As with the other realms of studies of the human hippocampus, resolving this issue requires difficult quantitative postmortem studies.

Obviously, many issues remain to be resolved and are likely to have some important consequences in neurology, psychiatry, and gerontology. Most broadly, the interrelated phenomena of GC neuroendangerment, inhibition of neurogenesis, dendritic atrophy, and neurotoxicity shift the realm of stress-related disease to the nervous system. For nearly 70 years, stress physiology has taught that cardiovascular function, metabolism, and immunity can be sensitive to the adverse effects of stress. This newer literature demonstrates that this vital and fragile portion of our bodies, the brain, can be sensitive to stress as well.

Mechanisms Controlling Glucocorticoid Secretion in Stress
Glucocorticoid Secretion in Repeated or Sustained Stress
Age- and Gender-Related Changes in the Stress Response

Glossary

Hypothalamo-hypophyseal portal vessels

A specialized portal blood system responsible for the transportation of neurohormones (termed releasing hormones) from the median eminence area of the hypothalamus to the anterior pituitary gland.

Paraventricular nuclei (PVNs)

Specialized areas of the hypothalamus lying on either side of the third ventricle; these nuclei include the cell bodies of neurons that project to the median eminence area of the hypothalamus, and they play a key role in initiating the pituitary-adrenal response to stress.

The glucocorticoids (cortisol and/or corticosterone, depending on the species) are steroid hormones produced by cells in the zona fasciculata of the adrenal cortex under the influence of the hypothalamic-pituitary complex (**Figure 1**). They exert diverse actions in the body and thereby play a key role in the regulation of crucial homeostatic mechanisms, such as those concerned with metabolic control and immune/inflammatory responses. The actions of the steroids are effected intracellularly, mainly via glucocorticoid receptors (GRs) but also via mineralocorticoid receptors (MRs). In normal circumstances, the rate of glucocorticoid secretion is maintained within narrow limits, varying according to a circadian rhythm that is coupled to the sleep-wake cycle; serum levels of the steroids are thus normally maximal at the end of the sleep phase and fall to a nadir some hours after waking. However, glucocorticoid secretion is increased markedly in conditions of physical and emotional stress; hence, the glucocorticoids are frequently termed stress hormones. The stress-induced changes in circulating glucocorticoids are superimposed on the existing circadian tone and vary in their rate of onset, magnitude, and duration according to the nature, duration, and intensity of the insult. Significant

Figure 1 The hypothalamic-pituitary-adrenal axis. Dotted lines indicate inhibitory influences; intact lines indicate stimulatory influences; the clock indicates circadian influences. ACTH, adrenocorticotropic hormone; AVP, arginine vasopressin; CRH, corticotropin releasing hormone.

interspecies variations also occur; for example, humans are particularly sensitive to emotional trauma, whereas rats respond very readily to physical stimuli such as cold and pigs are relatively unresponsive to many stimuli (e.g., histamine and cold) but show a marked elevation in serum cortisol when deprived of food.

Mechanisms Controlling Glucocorticoid Secretion in Stress

The Hypothalamic-Pituitary-Adrenocortical Axis

The release of the glucocorticoids in stress is orchestrated mainly by the hypothalamus, which receives and integrates neural and humoral information from many sources and initiates the release of two neurohormones, termed corticotropin releasing hormone (CRH) and arginine vasopressin (AVP), into the hypothalamo-hypophyseal portal vessels. These peptides are transported to the anterior pituitary gland via the portal vessels, where they act synergistically to cause the release of adrenocorticotropic hormone (ACTH), which, in turn, stimulates cortisol/corticosterone secretion. The hypothalamus thus provides a

vital link between the perception of physical and emotional stress and the regulation of key homeostatic mechanisms. The responsivity of the hypothalamic-pituitary-adrenocortical (HPA) axis to incoming stimuli is modulated by a servo system through which the sequential release of CRH/AVP and ACTH from the hypothalamus and anterior pituitary gland, respectively, is regulated negatively by the glucocorticoids themselves (Figure 1); the magnitude of the HPA response to stress thus depends on the preexisting glucocorticoid tone.

Adrenocorticotropic Hormone and Steroidogenesis

Cortisol and corticosterone are not stored to any great degree in the adrenal cortex but are synthesized on demand and promptly pass by diffusion across the cell membrane into the systemic circulation. The primary trigger for the synthesis of the steroids is ACTH, a polypeptide hormone produced by a specialized subgroup of cells in the anterior pituitary gland, the corticotrophs. ACTH acts via specific membrane-bound receptors, termed type 2 melanocortin (MC2) receptors, to activate the rate-limiting enzyme in the steroidogenic pathway; it thus causes the conversion of cholesterol to pregnenolone, from which cortisol and corticosterone are formed rapidly. In addition, ACTH acts on the vasculature to increase adrenal blood flow and thereby aid the passage of the newly synthesized steroids out of the cells and into the general systemic circulation. Increases in circulating glucocorticoids may be apparent within 10 min of the onset of the stress, although, in some instances (e.g., following an immune insult) the response may be delayed. Approximately 95% of cortisol/corticosterone in blood is protein bound, mainly to a specific high-affinity corticosteroid-binding globulin (CBG) but also to albumin, which has a lower affinity for the steroids. In principle, only the free steroid has ready access to the corticosteroid receptors (GRs and MRs), which are located intracellularly in the target cells. However, local mechanisms that release the steroid from its carrier protein(s) appear to exist in at least some target tissues; these include (1) interactions of the carrier protein with cell surface CBG receptors and (2) enzymatic cleavage of CBG (e.g., by serine proteases in inflamed tissues), a process that lowers the affinity of the binding protein for the steroids. The access of the steroids to their receptors is further regulated within the target cells by 11β -hydroxysteroid dehydrogenase (11β -HSD) enzymes, which control the interconversion of cortisol and corticosterone to their inactive counterparts, cortisone and 11 -dehydrocorticosterone. The biochemical half-life of the steroids is approximately 90 min, but

the biological effects may be sustained for very much longer. Metabolism is hepatic and the resulting metabolites are conjugated and excreted in the bile and the urine.

Synthesis and Secretion of Adrenocorticotrophic Hormone

ACTH is synthesized in the corticotrophs by the post-translational cleavage of a large precursor molecule, proopiomelanocortin (POMC). POMC also gives rise to a number of other peptides that are coreleased with ACTH and are termed collectively ACTH-related or POMC peptides. These include an N-terminal peptide, N-POMC(1–76), of unknown function and β -lipotropin (β -LPH), which, in turn, may be partially degraded to β -endorphin (which is sometimes used as a marker of ACTH secretion) and γ -LPH. In some circumstances (e.g., adrenal insufficiency), more extensive N-terminal processing may occur, either within the pituitary gland or at the adrenal level, generating peptides that appear to augment the steroidogenic capacity of the adrenal cortex by potentiating the steroidogenic response to ACTH (γ -melanocyte-stimulating hormone) or enhancing adrenocortical mitogenesis (N-POMC(1–46)).

ACTH is released from the anterior pituitary gland into the bloodstream in an episodic manner under the direction of hypothalamic CRHs. The frequency of pulses is normally fairly constant over the 24-h period, and it is changes in the amplitude that give rise to the circadian profile of ACTH and, hence, glucocorticoid secretion. Increases in pulse amplitude also underpin the stress-induced excursions in pituitary-adrenocortical activity although, in some instances, changes in pulse frequency may also occur.

Hypothalamic Control of Adrenocorticotrophic Hormone Secretion

The concept that the secretion of ACTH is driven by a neurohormone, termed corticotropin-releasing factor (CRF), that is released from the hypothalamus and transported to the pituitary gland via the hypothalamic-hypophyseal portal vessels was first recognized in the late 1940s by Harris. However, some 35 years elapsed between Harris's pioneering work and the identification of the active principles. By the late 1970s it was becoming apparent that CRF activity of the hypothalamus could not be ascribed to a single factor, and the concept of a multifactorial CRF rapidly gained credence. Subsequent work identified a 41-amino-acid residue neuropeptide, termed CRH, as the principal component and also pointed to a key role for AVP.

Corticotropin releasing hormone The 41-amino-acid neuropeptide, CRH, was first identified in ovine hypothalami by Vale and colleagues; the human peptide was identified subsequently and shown to differ from the ovine peptide by seven amino acids but to be identical to the rat peptide. The CRH gene is well characterized in the rat, mouse, and human and is expressed at multiple sites within the central nervous system (e.g., the hypothalamus, amygdala, and brain stem) and also in the periphery. CRH destined for the anterior pituitary gland is synthesized in the cell bodies of parvocellular neurons, which originate in the paraventricular nucleus (PVN) of the hypothalamus and project to the external lamina of the median eminence. These neurons terminate in close apposition with the capillaries of the hypothalamo-hypophyseal portal complex into which they release their secretory products for transportation to the anterior pituitary gland. The concentration of CRH in hypophyseal portal blood is high (vs. peripheral blood) and alters in parallel with perturbations of pituitary-adrenal function (e.g., stress), as also does the expression of the peptide and its mRNA in the PVN–median eminence tract. The actions of CRH on the corticotrophs are effected by specific type 1 CRH receptors (CRH-R1s), and the blockade of these receptors with selective antagonists attenuates corticotropic responses to specific stressors and to exogenous CRH. The stress response is also impaired in mice in which genes encoding either CRH or CRH-R1 are ablated, although resting ACTH levels appear to be normal in mutant mice. CRH-R1s are coupled positively to adenyl cyclase via a G_s -protein. The stimulation of the receptor therefore causes a rise in intracellular cAMP with subsequent activation of protein kinase A, which phosphorylates Ca^{2+} channels, thereby permitting Ca^{2+} influx and the release of ACTH by exocytosis. The activation of CRH-R1s in the pituitary gland also augments POMC gene expression and hence ACTH synthesis and, in the longer term, causes the proliferation of the corticotrophs.

Arginine vasopressin The ACTH-releasing activity of AVP was first recognized in the 1950s, and evidence that AVP may be an important component of a multifactorial corticotropin releasing complex emerged originally from studies performed in rats congenitally lacking AVP (Brattleboro strain) and was subsequently supported by work using specific antisera and antagonists to the peptide. AVP *per se* shows only weak ACTH-releasing activity, acting via the V1b subclass of AVP receptors, which use the phosphatidylinositol signal transduction system.

However, it also potentiates the corticotropic responses to CRH markedly and thus plays a key role in determining the magnitude of the stress response. Surprisingly, the biochemical basis of this important synergistic response is poorly defined, although it is apparent that the activation of the V1b receptor potentiates the accumulation of 3'5' cAMP induced by CRH, probably by a mechanism involving protein kinase C-dependent protein phosphorylation. AVP destined for the corticotrophs is derived primarily from a population of CRH-containing parvocellular neurons projecting from the PVN to the median eminence; thus, as for CRH, the concentration of AVP in the portal system is relatively high (vs. peripheral blood) and is increased further by stress. In addition, some AVP may be directed to the corticotrophs from magnocellular neurons of the neurohypophyseal system (the primary source of AVP in peripheral blood) via the interconnecting short portal vessels. Within the parvocellular system, CRH and AVP are colocalized in the same secretory granules and may therefore be cosecreted. However, histological studies suggest that not all CRH-positive neurons express AVP in normal circumstances, thus permitting the ratio of AVP : CRH released to vary in a stimulus-specific manner; equally, not all corticotrophs express receptors for AVP, thereby permitting another level of control. Although AVP is generally considered to be the second CRH, this is not always the case. For example, in the sheep, AVP has precedence over CRH; similarly, in rodents and possibly in humans, AVP appears to be the dominant factor driving ACTH release in conditions of repeated or sustained stress.

Other hypothalamic factors Other hypothalamic factors may also contribute to the regulation of ACTH, including the pituitary adenylyl cyclase-activating peptide (PACAP), which exerts a stimulatory influence, and atrial natriuretic peptide (ANP) and substance P, both of which exert inhibitory influences.

Stress-Induced Activation of Corticotropin Releasing Hormone/Arginine vasopressin Neurons

The parvocellular CRH/AVP neurons in the hypothalamus are well positioned to monitor, integrate, and respond to emotional insults and physical changes in the internal or external environment that threaten homeostasis (i.e., stress). Significantly, they receive inputs from many ascending and descending nervous pathways; in addition, they are sensitive to a variety of substances that may be relayed by the bloodstream or the cerebrospinal fluid (e.g., glucose and steroids) and to local factors released from interneurons or

glial cells (e.g., eicosanoids and cytokines). Major roles have been identified for (1) inputs from the brain-stem nuclei, particularly the nucleus tractus solitarius (NTS), that relay sensory information directly to the PVN and also to other parts of the brain and (2) pathways projecting to the PVN from the prefrontal cortex and the limbic system (hippocampus; amygdala; lateral septum; and the bed nucleus of the stria terminalis, BNST), but other pathways, such as those arising from raphe nuclei, are also likely to contribute. Although the precise complement of neural pathways, humoral substances, and local mediators that orchestrates the release of CRH/AVP in stress almost certainly depends on the nature of the stimulus and the status of the individual at the time of the stress, some classification according to the type of stress is now possible. For example, HPA responses to visceral homeostatic stressors that lack a cognitive component (e.g., acute hypotension) are initiated by afferent fibers that signal via the brain-stem nuclei and the noradrenergic pathways that project from the brain stem to the PVN; some homeostatic stressors also signal via humoral mechanisms; for example, the responses to hypoglycemia and hypertonicity involve intrahypothalamic glucose- and osmotic-sensitive neurons, respectively. Visceral stressors with a significant cognitive component (e.g., restraint, foot shock, or cold) use somatosensory afferents and central pathways involving both the brain-stem nuclei and the corticolimbic system to activate the PVN. The corticolimbic system also plays a fundamental role in effecting the HPA responses to emotional stressors; the importance of the hippocampus, which is critical to cognitive function, particularly learning and memory function, is well documented in this regard, as is the role of the amygdala, a key area in coordinating the behavioral, autonomic, and neuroendocrine responses to fear or anxiety.

Challenges to the host defense system, such as those provoked by infection, injury, or inflammation, pose a major threat to homeostasis and thus constitute a severe stress. Not surprisingly, in experimental animals and in humans the HPA axis responds to such insults with a marked increase in its activity. This response is driven by the army of mediators (e.g., interleukins, eicosanoids, histamine, and phospholipase A2) released from the activated immune/inflammatory cells. Some of these agents may target the HPA axis directly, acting mainly at the hypothalamic level to trigger CRH/AVP release but also on the anterior pituitary gland and adrenal cortex to augment or sustain the final adrenocortical response. Others may act locally at the site of the infection or inflammatory lesion to stimulate sensory fibers and

thereby activate the central pathways that precipitate CRH/AVP release. In addition, many of the mediators provoke widespread pathological effects in the body (e.g., hypotension or hypoglycemia), which themselves stimulate the axis by the mechanisms outlined earlier. The HPA response to immune insults is thus a complex event potentially requiring the integration of a broad spectrum of stimuli, the complement of which reflects the nature and intensity of the insult. Much research has focused on the influence of the cytokines, interleukin (IL)-1 β and IL-6, which are particularly important in initiating the HPA response to bacterial and viral infections. Three main mechanisms have been proposed to explain their actions.

1. The cytokines act directly on the PVN to trigger CRH release via a mechanism dependent on prostanoid generation. This mechanism has been refuted on the basis that the cytokines, which are large polypeptides (17–26 kDa), are unlikely to penetrate the blood–brain barrier and thereby gain access to their targets. However, the possibility that cytokines enter the brain via fenestrated regions of the barrier (e.g., organum vasculosum lamina terminalis, OVLT), areas in which the permeability is increased by local inflammation, or the recently described transporter system cannot be discounted.

2. The cytokines act at the level of the blood–brain barrier itself, exerting prostanoid-dependent actions on the endothelium that trigger CRH/AVP release by mechanisms that may include the activation of neural pathways and/or induction of *de novo* synthesis of cytokines in the hypothalamus and elsewhere in the brain that are required to drive the neuroendocrine response. This concept is supported by the presence of IL-1 receptors in the endothelial cells and by increased IL-1 mRNA expression in the hypothalamus and other brain areas of rodents subjected to endotoxin challenge.

3. Hypothalamic responses to peripheral cytokines involve the sequential activation of sensory fibers, brain-stem nuclei (notably the NTS), and the ventral noradrenergic pathways (and possibly others) to the PVN. This view concurs with claims that the expression of IL-1 β mRNA in the hypothalamus and the hypersecretion of ACTH release induced by endotoxin are both dependent on the integrity of the vagus and that HPA responses to local inflammatory lesions induced by turpentine require C fibers. However, it is at odds with reports that cytokines activate the NTS, and hence connections between the NTS and the PVN, by mechanisms that are independent of the vagus but which may involve local prostanoid-dependent interactions with the blood–brain barrier.

Negative Feedback Control of the Hypothalamic-Pituitary-Adrenal Axis

Role of glucocorticoids Adrenocortical responses to incoming stimuli are effectively contained within appropriate limits by the glucocorticoids themselves, which exert powerful inhibitory influences on the secretion of ACTH and its hypothalamic-releasing hormones. Thus, elevations in circulating glucocorticoid levels brought about, for example, by the administration of exogenous steroids effectively suppress the HPA responses to stress and also the circadian rise in pituitary-adrenocortical activity. Conversely, the ACTH response to stress is exaggerated in subjects with adrenocortical insufficiency (e.g., Addison's disease) but corrected by glucocorticoid replacement therapy. The feedback actions of the steroids are highly complex because they are exerted at multiple sites within the axis, effected by multiple molecular mechanisms, and operate over three time domains: rapid or fast feedback, early delayed feedback, and late delayed feedback.

Phases of steroid feedback Rapid feedback develops within 2–3 min of an increase in glucocorticoid levels. It is of short duration (<10 min) and is followed by a silent period during which the stress response is intact, even though the circulating steroid levels may remain elevated. Rapid feedback is sensitive to the rate of change rather than the absolute concentration of steroid in the blood and may therefore provide an important means whereby the HPA response to stress is terminated; alternatively, it may serve to blunt the responses to a second stress incurred at a time when the steroid levels are still rising in response to the first stress. The early delayed phase of feedback develops approximately 0.5–2 h after an acute elevation in plasma steroid levels. It is normally maximal within 2–4 h and, depending on the intensity of the stimulus, may persist for up to 24 h. Both the circadian and the stress-induced excursions in ACTH secretion are suppressed with an intensity that is directly proportional to the concentration of steroid previously reached in the blood. Late delayed feedback, which has a latency of approximately 24 h, develops only after a very substantial rise in steroid levels and is frequently the consequence of repeated or continuous administration of high doses of corticosteroids. It may persist for days or weeks after the steroid treatment is withdrawn and is thus largely responsible for the potentially life-threatening suppression of the HPA axis associated with abrupt cessation of long-term treatment with high doses of steroids in, for example, rheumatoid arthritis.

Mechanisms of glucocorticoid feedback The rapid feedback actions of the glucocorticoids are exerted primarily at the hypothalamic level; weaker actions also occur at the pituitary level, but the contribution, if any, of extrahypothalamic sites in the central nervous system is ill defined. The underlying molecular mechanisms are poorly understood. Although there are some reports to the contrary, the majority of data suggests that these effects are nongenomic (and hence do not involve MRs or GRs) and that they may be mediated by receptors that are located close to or within cell membranes and which, when activated, inhibit exocytosis, possibly by blocking Ca^{2+} . In contrast, the early and late delayed phases of feedback inhibition are mediated by classic intracellular corticosteroid receptors located primarily in the anterior pituitary gland, the hypothalamus, and the hippocampus, but also elsewhere in the brain. Both the high-affinity MRs and the lower-affinity GRs are involved. Current evidence suggests that MRs (located predominantly in the hippocampus) may maintain the tonic inhibitory influence of steroids on HPA function in nonstress conditions because these receptors, which are not protected by $11\beta\text{-HSD}$, are normally almost fully occupied by glucocorticoids, even at the nadir of the circadian rhythm. GRs, however (found in particular abundance in the anterior pituitary gland and hypothalamus) are occupied extensively only when the glucocorticoid level is raised by stress, disease, or the administration of exogenous steroids; thus, unlike MRs, these receptors serve to detect phasic changes in steroid levels and to adjust the activity of the HPA axis accordingly. Early delayed feedback requires the *de novo* generation of protein second messengers that serve to inhibit the release of ACTH and its hypothalamic-releasing factors; several proteins are likely to be involved, including lipocortin 1 (LC1, annexin 1), a Ca^{2+} - and phospholipids-binding protein strongly implicated in the anti-inflammatory and antiproliferative actions of the steroids. The genes encoding POMC in the pituitary gland and CRH/AVP in the parvocellular PVN neurons may also be repressed during the early delayed phase of feedback; however, the consequent downregulation of ACTH, CRH, and AVP synthesis emerges relatively slowly and, with existing techniques, is not normally discernible until some hours after the onset of inhibition of peptide release. Late delayed feedback is characterized by the inhibition of the synthesis and the release of CRH/AVP and ACTH in the hypothalamus and anterior pituitary gland, respectively. The inhibition of synthesis again reflects the inhibitory influence of the steroids on the genes encoding each of the three peptides, but

the concomitant inhibition of peptide release cannot be explained fully in this way because peptide stores are rarely fully depleted.

Short loop and ultrashort loop feedback mechanisms

In addition to the corticosteroids, other hormones of the HPA axis participate in the feedback regulation of ACTH secretion. Of particular importance are the POMC-derived peptides, ACTH and β -endorphin, both of which have been shown to exert powerful inhibitory actions on the secretion of CRH/AVP by the hypothalamus. Because neither peptide penetrates the blood-brain barrier readily, their short loop feedback actions are probably exerted at the level of the median eminence, which lies outside the blood-brain barrier. Ultrashort loop feedback actions have been attributed to both CRH and AVP, but the physiological significance of such responses is unclear.

Glucocorticoid Secretion in Repeated or Sustained Stress

The bulk of studies on stress and HPA function have focused on acute stresses, and relatively little is known of either the characteristics or the mechanisms controlling the HPA responses to repeated or sustained stress. Such conditions are, of course, inherent to our lifestyle and environment, and a deeper understanding of their influence on neuroendocrine function is thus highly desirable. However, for both ethical and practical reasons, it is difficult to develop appropriate animal models and, as described later, the available data suggest that the profile of the HPA responses observed may vary considerably according to the nature of the stress.

In some cases, HPA responses to repeated (successive or intermittent) or sustained (chronic) stressful stimuli are attenuated. For example, tolerance develops to stresses such as cold, handling, saline injection, or water deprivation (induced by the replacement of drinking water with physiological saline). Some degree of cross-tolerance may occur between stresses that invoke similar pathways/mechanisms to increase CRH/AVP release. Thus, for example, repeated handling reduces the subsequent adrenocortical response to a saline injection; however, rats tolerant to the C fiber-dependent stress of exposure to a cold environment respond to the novel stress immobilization with a normal or even exaggerated rise in serum corticosterone. In other situations, however, tolerance does not develop; thus, HPA responses to intermittent stresses of electric foot shock, insulin hypoglycemia, or $\text{IL-1}\beta$ are maintained or even enhanced, as are those to the chronic stress of septicemia.

The sustained release of ACTH in repeated/chronic stress appears to be driven mainly by AVP. Thus, in rats subjected to repetitive foot shock, brain surgery, or injection of IL-1 β or lipopolysaccharide (LPS), AVP is synthesized in and released from parvocellular neurons in the PVN in preference to CRH; in addition, the sensitivity of the pituitary gland to AVP is well maintained, whereas that to CRH is reduced. Similarly, the expression of AVP, but not CRH, in the parvocellular PVN is increased in rats with experimentally induced arthritis; moreover, although the arthritic rats respond to LPS with a rise ACTH secretion, they are relatively unresponsive to a novel neurogenic stress normally driven mainly by CRH. The switch to AVP as the principal driving force to the corticotrophs in repetitive/chronic stress may reflect the disruption of the negative feedback mechanism for the expression of MRs in the hippocampus, and GRs in the PVN are reduced in conditions of chronic stress; moreover, the capacity of dexamethasone to block the HPA response to IL-1 β is impaired in rats pretreated 3 weeks with the cytokine. In the same vein, AVP and disrupted feedback have both been implicated in the etiology of the hypercortisolemia evident in depression, although others have advocated a role for CRH.

Age- and Gender-Related Changes in the Stress Response

Development

The functional development of the HPA axis begins in fetal life, and in the later stages of gestation the fetus secretes substantial quantities of cortisol/corticosterone. It also responds to stress with increases in adrenocortical activity, which are driven by the hypothalamic-pituitary axis and which are sensitive to the negative feedback actions of the glucocorticoids. Paradoxically, in the rat and several other species, HPA function regresses postnatally and a period ensues during which the ability of the axis to respond to stress is compromised. In the rat, this stress hyporesponsive phase (SHRP) normally persists from postnatal day 5 (P5) to P14, although depending on the stimulus a mature stress response may not emerge for up to 5–6 weeks. The refractoriness of the HPA axis to stress in the SHRP is not absolute and may be at least partially overridden in certain cases. For example, IL-1 β , hypoglycemia, glutamate, and histamine all elicit modest rises in serum ACTH and corticosterone throughout this period. Exceptionally, the hypersecretion of ACTH provoked by LPS in the SHRP matches that observed in the adult, although the

associated rise in serum corticosterone does not; moreover, paradoxically, both the ACTH and the corticosterone responses to kainic acid are more robust at P12 than P18. These and many other data suggest that the processes involved in the maturation of the stress response are complex and stimulus-dependent. They are therefore likely to involve a variety of factors that act in concert at different levels of the axis during the developmental period. These include immaturity of the neural and humoral mechanisms effecting the release of CRH/AVP in stress, enhanced sensitivity of the axis to the regulatory actions of the glucocorticoids, and impairment of the synergy between CRH and AVP.

Perinatal Programming of the Stress Response

Glucocorticoids play a key role in developmental programming, and a growing body of evidence suggests that inappropriate exposure of the developing fetus/neonate to the steroids or to factors that influence the expression/function of their receptors may trigger a plethora of pathologies (e.g., growth retardation or impairment of central nervous system development) and predispose the individual in later life to conditions as diverse as hypertension, insulin resistance, cognitive and other behavioral disorders, and allergic/inflammatory disease. Because the SHRP coincides with an important phase of development, it seems likely that it may serve to protect the organism from the potentially harmful effects of overexposure to glucocorticoids.

Despite its tight control, the developing HPA axis exhibits a high degree of plasticity, and disturbances in its activity at critical stages of development precipitate abnormalities in glucocorticoid secretion that persist into adult life and may increase the susceptibility of the individual to disease. Perinatal manipulations that alter the expression of GRs (but not MRs) in the brain are particularly hazardous in this regard because, by disrupting the negative feedback mechanisms, they alter the responsiveness of the HPA axis to stress throughout the lifetime of the individual. For example, exposure of neonatal rats to dexamethasone or LPS results in the adult in downregulation of GRs in the hippocampus and hypothalamus, decreased sensitivity of the HPA axis to the negative feedback actions of the glucocorticoids, and exaggerated HPA responses to stress. Similar long-term changes in GR expression occur in rats subjected to prolonged periods of maternal separation; the consequent impairment of the negative feedback system and changes in HPA function are associated with alterations in T-cell antibody responses and in the incidence

of age-related neuropathies. In contrast, neonatal handling, which increases hippocampal GR expression by mechanisms involving serotonin, reduces the magnitude and duration of the stress response in the adult; maternal care may therefore help program events that regulate responses to stress in the adult and thus reduce vulnerability to disease.

Sexual Dimorphism in Hypothalamic-Pituitary-Adrenal Function

In adults, distinct sexually dimorphic patterns of glucocorticoid secretion emerge. Serum glucocorticoid concentrations are consistently higher in the female than in the male, with further increases occurring toward the middle of the menstrual/estrous cycle just prior to ovulation and in the late stages of pregnancy. These changes are due partly to the positive effects of estrogen on the expression of CBG. In addition, estrogen exerts significant effects at the hypothalamic level, increasing the synthesis and release of CRH, a phenomenon that may be implicated in the etiology of the relatively high incidence of emotional disorders (e.g., depression and anxiety) in the female that are characterized by enhanced CRH secretion. Further modulation may be brought about by progesterone, which, when present in large amounts (e.g., in the premenstrual phase or pregnancy), binds readily to but is only weakly active at MRs in the hippocampus.

Stress Responses in the Aging

In both sexes, serum glucocorticoid concentrations tend to increase in aging individuals, particularly in disease states; in addition, although sometimes delayed, the HPA responses to stress are frequently exaggerated and prolonged. This aging process has been attributed in part to the downregulation of the corticosteroid receptors (GRs and MRs) in the hippocampus and hypothalamus and to the consequent emergence of a resistance of the HPA axis to the negative feedback actions of the glucocorticoids. The consequences are potentially important because hyperglucocorticoidemia is considered to be an important contributory factor in a number of age-related diseases, including neurodegenerative conditions, cognitive dysfunction, osteoporosis, noninsulin-dependent diabetes mellitus, and the decline in immunocompetence.

Glossary

Glucocorticoids

(From Greek *γλυκος* meaning sweet and Latin *cortex* meaning bark.) Steroids produced by the adrenal cortex which regulate carbohydrate metabolism; however their actions are by no means confined to carbohydrate metabolism.

Steroids

Chemicals containing the cyclopentanoperhydrophenanthrene nucleus ([Figure 1](#)).

Introduction

Chemistry

Structurally glucocorticoids (GCs) are all modifications of corticosterone ([Table 1](#)). Modifications which enhance activity include the addition of a 17 α -hydroxy group (cortisol, [Figure 2](#)), a Δ 1-double bond (prednisolone), a 9 α -fluoro (fludrocortisol), a 16 α - or 16 β -methyl or a 16 α -hydroxy group. The 11-keto analogs of these compounds are often included because, although they themselves are biologically inactive, they are readily converted to the active 11-hydroxylated forms. Cortisone, the 11-keto derivative of cortisol, was identified before cortisol, so that for many years cortisol was known as hydrocortisone (i.e., cortisone), with two additional hydrogens giving the 11-hydroxyl group. Oral cortisone and prednisone, the 11-keto analog of prednisolone, are widely

used therapeutically since they are about 80% converted to the active forms as they pass through the liver after absorption in the gastrointestinal tract.

History

In the late 1930s and early 1940s many steroids were isolated from the adrenal cortex of animals and man. Glands from 20 000 cattle were collected to give 1000 kg of tissue from which 25 g of material was further processed to determine more than 30 different steroids, including the GCs and mineralocorticoids.

Evolution

Steroids are present throughout the whole of the biosphere of the Earth, and are thought to be ancient bioregulators, present throughout the plant and animal kingdoms, which evolved prior to the appearance of eukaryotes. They seem to be primordial biomolecules which are among the earliest chemical information transmitters and have had a crucial role in the evolution of life. Even bacteria, viruses, and blue-green algae contain steroids.

GCs are secreted in all vertebrates, but not in other life forms. In mammals and bony fish, the main GC is cortisol, except in some rodents where it is corticosterone. In birds, reptiles, amphibians, and cartilaginous fish, the main GC is corticosterone.

Binding Proteins

There are two types of binding proteins for steroids: one type which inactivates them, and the other which activates them.

Transport Proteins

Corticosteroid-binding globulin (CBG), present in blood, binds GCs noncovalently in such a way that their biological activity is suppressed; thus it is the

Figure 1 Cyclopentanoperhydrophenanthrene nucleus.

Table 1 Modifications of corticosterone to give other glucocorticoids, and their relative potencies in humans

Steroid	Modification of corticosterone	Anti-inflammatory potency	Salt-retaining potency	LHPA-axis suppression
Corticosterone	—	0.35	15	
Cortisol	17 α -OH	1	1	1
Prednisolone	Δ^1 -, 17 α -OH	4	0.75	4
Methylprednisolone	6 α -methyl-, Δ^1 -, 17 α -OH	6	0.5	4
Fludrocortisol	9 α -fluoro-, 17 α -OH	15	280	
Dexamethasone	16 α -methyl-, Δ^1 -, 9 α -fluoro-, 17 α -OH	26	<1	17
Betamethasone	16 β -methyl-, Δ^1 -, 9 α -fluoro-, 17 α -OH	25	<1	
Triamcinolone	16 α -hydroxyl-, Δ^1 -, 9 α -fluoro-, 17 α -OH	5	<1	4

A dotted line denotes that the C17 OH is below the plane of the molecule, while a straight line, as for the C18- or C19-hydroxyl denotes that the CH₃ is above the plane. Asterisks indicate asymmetric carbon atoms. Bottom: Depicted in the customary fashion and showing numbering of the carbon atoms.

unbound or free hormone which is active. These proteins are found in virtually all vertebrates and their specificities for GCs vary; in some cases the binding is very highly specific and can be used to measure the steroid that is bound. They are saturable so that at high levels of GCs, proportionally less is bound. Such proteins are important in the transport of GCs since they prevent undue transfer of the steroid into tissues where it would be subject to enzymatic action and/or degradation. They thus provide a reservoir to damp down rapid changes. In conditions of severe stress, they are reduced. GCs are also bound reversibly and noncovalently to albumin, but this is a nonspecific and loose type of binding.

Glucocorticoid Receptors

Another kind of protein that binds GCs is the GC receptor (GR), which mediates the action of the

steroid and is found in or on the target cells for the hormones. This binding is of high affinity and specificity and is saturable. In the nucleus, the hormone-receptor complex is activated and binds to deoxyribonucleic acid (DNA), leading to transcription.

The actions of GCs are mediated by two types of receptors: GRs and mineralocorticoid receptors (MRs). GRs bind GCs but not aldosterone, while MRs bind both GCs and aldosterone, the selectivity of the MRs being dependent upon the presence of 11 β -dehydrogenase (particularly in the kidney) to inactivate the GCs. In the hippocampus where MRs are present in high concentrations, GCs serve to activate both.

Biosynthesis

The synthetic pathway appears to be much the same throughout the vertebrates: acetate $\rightarrow$ cholesterol $\rightarrow$ pregnenolone $\rightarrow$ corticosterone and/or cortisol (Figure 3). Each step is catalyzed by an enzyme. Some of these enzymes are known to occur also in plants and bacteria.

Steroidogenic tissues can take up low-density lipoprotein cholesterol from the plasma (about 80%), mobilize intracellular cholesterol ester pools, or synthesize cholesterol *de novo* from acetate. GCs are synthesized from cholesterol by the P450 group of enzymes (oxidative enzymes that have a characteristic 450-nm absorbance maximum when reduced with carbon monoxide). The first step is achieved by P450_{SCC}, the side-chain cleavage (SCC) enzyme, which cleaves the side chain from the C20 to give pregnenolone. This occurs in the inner mitochondrial membrane. 21-Hydroxylation occurs in the smooth endoplasmic reticulum while 11-hydroxylation occurs in the mitochondrion. In humans, the route to corticosterone and aldosterone production takes place in the adrenal zona glomerulosa while that to cortisol occurs in the zona fasciculata and the reticularis; the 11-hydroxylating enzymes involved differ slightly in the two regions, while the P450_{C17}-hydroxylase is

Figure 3 Biosynthesis of adrenal corticosteroids. 3 α -HSD, 3 α -hydroxysteroid dehydrogenase; 5 β -HSD, 5 β -hydroxysteroid dehydrogenase.

lacking in the zona glomerulosa. The P450_{C17} enzyme also cleaves the C20–C21 from C17, giving rise to dehydroepiandrosterone (DHEA) and the adrenal androgen pathway. If the GC pathway is blocked, as in congenital adrenal hyperplasia, this route becomes prominent. DHEA is sulfated in the reticularis to give DHEA sulfate (DHAS), which is quantitatively, though not physiologically, the most important product of the adult adrenal cortex.

In fetal primates, the adrenal is relatively much larger than in the adult, and is made up mainly of a fetal zone which is lost at about the time of birth. This zone lacks 3 β -hydroxysteroid dehydrogenase isomerase so that the major steroid produced by this zone is DHEA, mainly in the sulfated form. The function of this zone remains speculative.

Actions

GCs are necessary for life and affect every cell of the body. They are thought to enter the cell mainly by passive diffusion, and then bind to the GR. They also act nongenomically at membrane receptors.

Carbohydrate Metabolism

Adrenalectomized animals become hypoglycemic because they cannot maintain their hepatic glycogen stores. GCs activate glycogen synthase and inactivate the phosphorylase which mobilizes glycogen. Although glucagon and epinephrine are also gluconeogenic, they are ineffective in the absence of GCs which act permissively.

GCs enhance gluconeogenesis from protein, thereby raising blood glucose and repleting liver glycogen. This is accomplished by increasing release of glucogenic amino acids from peripheral tissues such as skeletal muscle. GCs also activate gluconeogenic enzymes, including glucose-6-phosphatase and phosphoenolpyruvate carboxykinase. Large amounts result in negative nitrogen balance, and if prolonged, depletion of body protein, observed clinically as thinning of the skin, muscle wasting, myopathy, osteoporosis, and in children, retarded growth.

Fat Metabolism

GCs, administered acutely, activate lipolysis in adipose tissue, so that plasma free fatty acid levels are reduced. However, when given chronically, increased availability of carbohydrate produces an antiketogenic effect, and clinically a redistribution of fat from the extremities to the face and trunk, especially in the supraclavicular and dorsocervical areas, the latter producing the characteristic buffalo hump seen in Cushing's syndrome.

Electrolyte and Water Metabolism

Although much less potent than the mineralocorticoids, GCs in high doses may produce sodium and water retention, hypokalemia, and hypertension. Conversely, in their absence, there is renal sodium wasting, with a concomitant loss of water, hemoconcentration, hyponatremia, and hypovolemia. Hypotension may occur, although this is usually avoided if sufficient mineralocorticoid is present. Vasopressin (VP) is increased and free water clearance is decreased in GC insufficiency, which may help to maintain normal blood pressure. GCs stimulate plasma atrial natriuretic peptide (ANP) production, and potentiate ANP action on the kidney.

Immunologic Function and Inflammation

GCs alter immune responses and inhibit inflammatory reactions. These actions can have both beneficial and deleterious results. While GCs are essential to maintain life in the face of stressors, excessive GCs may cause reactivation of latent infections such as tuberculosis. In contrast, they may benefit autoimmune diseases. A local inflammatory response involves the movement of cells and fluid to the site of inflammation. Histamine, a potent vasodilator, is released at the site, and prostaglandins are involved. Within 4 h after a rise in GCs in response to stress, peripheral lymphocyte and monocyte numbers fall, but granulocytes enter the circulation from lymphatic tissues and sites of inflammation. GCs inhibit synthesis of cytokines, proliferation of monocytes and their differentiation into macrophages; they also inhibit the phagocytic and cytotoxic functions of macrophages.

Effects on Bone and Connective Tissue

If GC excess is prolonged, osteopenia occurs because GCs inhibit osteoblast function – including down-regulation of insulin-like growth factor I (IGF-I) which promotes osteoblast proliferation – thereby decreasing new bone formation. Osteoclast numbers and activity are increased. Intestinal calcium absorption is decreased and parathyroid hormone levels are secondarily increased; these effects can be reversed by giving vitamin D and calcium. Renal calcium reabsorption is decreased resulting in an increase in calcium excretion, and which may cause the formation of renal stones.

Since GCs also suppress synthesis of the extracellular matrix components collagen and hyaluronidate, clinically excessive GCs can impair wound healing and make connective tissue more friable, resulting in easy bruisability.

Oral administration of GCs may be associated with symptoms of gastric or duodenal ulcer; possibly this is

only apparent, as ulcers caused by other factors, and which would heal if left alone, may become clinically troublesome if wound healing is impaired.

Neuropsychiatric Effects

GCs are released during learning and are necessary for establishment of an enduring memory. However excessive amounts impair spatial learning. Such processes involve the hippocampus.

Cortisol increases brain excitability, and emotional disturbances and even psychoses may occur in states either of deficiency or excess. In states of GC excess – either endogenous as in Cushing's syndrome or exogenous from therapeutic administration – altered behavior has been frequently noted.

Interestingly, in adrenal insufficiency, depression is also common, usually in association with apathy and lethargy; it improves with GC replacement.

The actions of GCs in the brain are mediated both genomically, whereby they enhance transcription, and nongenomically by direct effects on the excitability of neuronal networks, especially in the hippocampus, where GRs are present in the highest density. They can affect many neurotransmitter systems, including noradrenergic, serotonergic, cholinergic, dopamine, and GABAergic activity.

Development

Excessive concentrations of GCs, either endogenous or exogenous, inhibit skeletal growth in children. In the human fetus, the concentrations of circulating and tissue cortisol are kept low by the action of 11 β -hydroxysteroid dehydrogenase type 2, which converts cortisol to inactive cortisone in almost all tissues until close to birth.

However GCs are important in stimulating differentiation of many cell types. In lung, they induce surfactant production, which is necessary for infant mammals to adapt to air-breathing at birth. GCs cause differentiation of the neural crest precursor cells of the adrenal medulla to differentiate into chromaffin cells which produce catecholamines.

Metabolism

Steps Involved

The GCs are metabolized primarily in the liver, and are excreted mainly through the kidneys in a series of steps catalyzed by enzymes ([Figure 4](#) and [Table 2](#)). These include:

1. Oxidation of the C11-hydroxyl to a ketone – the only reaction which is readily reversible

2. Reduction of the double bond at C4–5 to give 5 α - and, mainly 5 β -dihydro derivatives – these are almost entirely further reduced at the 3-ketone
3. Reduction of the 3-ketone to give 3 α (mainly) and 3 β -tetrahydro derivatives, which are in part further reduced at the C20-ketone
4. Reduction of the C20-ketone to give 20 α - and (mainly) 20 β -derivatives of any of the above compounds, but mainly of the tetrahydro derivatives to give the cortols (retaining the 11 β -hydroxyl group) and cortolones (with the 11-ketone group)
5. Cleavage of the side chain of tetrahydrocortisol to give etiocholanolone
6. Oxidation of the 21-OH of the cortols to give the cortolic acids, and of the cortolones to give the cortolonic acids
7. Conjugation of the various metabolites with glucuronic acid (mainly at the 3 β -hydroxyl) or sulfate (mainly 3 α -hydroxyl), rendering the steroids more water-soluble
8. 6 β -Hydroxylation of cortisol to give 6 β -hydroxycortisol, also a much more water-soluble steroid

Factors Affecting Hepatic Metabolism

The following factors affect hepatic metabolism.

1. Thyroid hormones influence the rates of metabolism. In hyperthyroidism, metabolism of GCs is accelerated, while the opposite occurs in hypothyroidism. While these changes affect urinary excretion of metabolites, plasma corticoid levels are maintained, owing to the feedback mechanism which remains unaltered
2. In states of GC excess, hydroxylation to 6 β -hydroxycortisol increases
3. In old age, corticoid metabolism decreases to some extent, while clearance of glucuronides is decreased; plasma levels usually rise slightly
4. In cirrhosis of the liver, 5-reduction is decreased
5. In obesity, greater amounts of metabolites are excreted, but the plasma levels remain essentially unchanged
6. Various drugs affect metabolism, e.g., rifampin accelerates metabolism, particularly to 6 β -hydroxycortisol. Phenytoin, phenobarbital, and mitotane all divert metabolism toward 6 β -hydroxycortisol

Extrahepatic Metabolism of Glucocorticoids

The kidney is another important site of metabolism, since its 11 β -hydroxysteroid dehydrogenase (type 2) converts cortisol to cortisone, thereby limiting access of cortisol to the MR which binds both aldosterone

and cortisol equally. Since aldosterone is present in much smaller amounts than cortisol, this permits aldosterone to exert its physiological action on the receptor. Genetic or pharmacologic alterations in the enzyme may cause mineralocorticoid problems.

Absorption

While steroids are generally administered via the oral route, they can be given effectively in many other ways including percutaneous, vaginal, rectal, nasal, and pulmonary, as well as intravenously, subcutaneously, and intramuscularly.

Intravenously administered steroids are diluted throughout the whole blood volume within a few minutes; subcutaneously injected steroids are absorbed within minutes to a few hours; intramuscularly

injected steroids are more slowly absorbed, particularly if diluted in a medium which slows absorption, in which case absorption may be delayed for days to weeks. Absorption through skin (especially damaged skin) is rapid – usually detectable 30–100 min after application, and maximal by 16–24 h.

Regulation of Levels of Glucocorticoids

The Limbic-Hypothalamic-Pituitary-Adrenal Axis

Stimuli reaching the brain from extracerebral sites impact on the limbic system, where they are relayed to the hypothalamus, causing stimulation of corticotropin-releasing hormone (CRH) and VP. CRH and VP pass via the portal blood to the pituitary, causing pro-opio-melanocortin to be processed into adrenocorticotrophic hormone (ACTH), endorphin, and other peptides, which enter the systemic circulation. ACTH stimulates the adrenal to produce cortisol and/or corticosterone which in turn feed back on GRs in the limbic system (principally the hippocampus and amygdala), hypothalamus, and pituitary to quench the stimulation, thus maintaining an ever-changing but essentially constant equilibrium (Figure 5).

Adrenocorticotropin ACTH acts by increasing synthesis of GCs, since adrenal storage of corticoids is minimal. ACTH stimulates the processing of cholesterol to Δ^5 -pregnenolone, the rate-limiting step

in synthesis. It does this by binding to specific cell-surface receptors present on the adrenal cells, which activates adenylate cyclase thereby increasing cyclic adenosine monophosphate (cAMP), in turn activating cAMP-dependent protein kinase and phosphorylation of a number of proteins. If stimulation continues for more than a few minutes, increased synthesis of the various enzymes of the steroidogenic pathway are stimulated, as well as cell growth; if prolonged, the adrenal hypertrophies. Conversely, if ACTH levels fall for a prolonged period of weeks or months, the adrenal atrophies.

Other possible stimulators include direct effects of cytokines on the adrenal cortex and stimulation through neural connections.

Dexamethasone suppression test The dexamethasone-suppression test is often used to assess the suppressibility of the limbic-hypothalamic-pituitary-adrenal (LHPA) axis in humans; most commonly a 1 mg dose is given at bedtime, and blood samples are drawn once or more during the next day. The test is considered normal if the levels fall below 140 nmol l^{-1} ($5 \text{ } \mu\text{g dl}^{-1}$), or preferably below 60 nmol l^{-1} ($2.2 \text{ } \mu\text{g dl}^{-1}$).

Insulin tolerance test The insulin tolerance test is commonly used to evaluate the integrity of the LHPA axis. It measures the response to hypoglycemia induced by giving an injection of insulin, usually 1 μg ,

Figure 5 The limbic-hypothalamic-pituitary-adrenal (LHPA) axis. CRH, corticotropin-releasing hormone; VP, vasopressin; POMC, pro-opiomelanocortin; ACTH, adrenocorticotrophic hormone; β -END, β -endorphin.

and following glucose and GC levels at 30, 60, and 90 min after injection. With normal CBG levels, the cortisol level should reach at least 500 nmol l^{-1} ($18 \text{ } \mu\text{g dl}^{-1}$).

Plasma Levels of Glucocorticoids under Various Conditions

Plasma levels of GCs are generally in the range of 10–1000 nM. They vary diurnally, being highest shortly after awakening, and gradually falling during the period of activity (e.g., during the night in rodents, during the day in humans and monkeys). Plasma levels among species vary depending on the affinity and level of their CBG in plasma and of the GRs in the hippocampus, hypothalamus, and pituitary. GCs are also present in red blood cells in appreciable amounts.

In humans in the unstressed state, the plasma level of cortisol is $50\text{--}600 \text{ nmol l}^{-1}$ during the day, being highest at 6–7 a.m. and lowest at midnight; corticosterone levels are about 10% of these and cortisone levels about 20%. Levels of cortisol in squirrel monkeys are higher at about 3000 nmol l^{-1} although their CBG levels are virtually undetectable. In rats, cortisol is absent, and corticosterone ranges at $50\text{--}200 \text{ nmol l}^{-1}$. Levels of corticosterone in fish (e.g., $15\text{--}200 \text{ nmol l}^{-1}$ in trout) and reptiles are somewhat lower. In salmonids, and many animals, cortisol levels change seasonally, often in conjunction with CBG levels. In stressed animals, the levels of GCs rise within minutes to levels up to 10 or more times the resting levels.

Levels of Glucocorticoids in Other Tissues

GC levels in brain are as high or higher than those of plasma because brain is a fatty tissue and GCs are very fat soluble. GCs are found in all tissues but levels are usually lower than those in plasma and lymph. Levels are low in cerebrospinal fluid because the CBG level is low. They are very high in the adrenal cortex, the site of synthesis.

Cortisol–Cortisone Interconversion

Although in adult humans the level of cortisol greatly exceeds that of cortisone, the reverse is true in fetuses where oxidation by 11β -hydroxydehydrogenase (11β -HSD) greatly exceeds reduction. 11β -HSD consists of two enzymes: type 1 which predominates in adult liver and converts cortisone to cortisol; and type 2 which predominates in adult kidneys, allowing aldosterone to act in the presence of a 100-fold molar excess of circulating cortisol by converting cortisol

to cortisone. This type is also high in skin, salivary glands, and nonpregnant uterus.

In the fetus, type 2 predominates in all tissues except liver and intestine. It is particularly high in the placenta, converting maternal cortisol to cortisone, and corticosterone to 11-dehydrocorticosterone. This conversion, which inactivates cortisol and corticosterone, protects the fetus from excessive GCs which would interfere with growth. Type 2 11β -HSD is inhibited by licorice. The same enzyme converts prednisolone to prednisone but does not act on dexamethasone.

The human uterus, though oxidative in the non-pregnant state, becomes strongly reductive in late pregnancy, increasing the cortisol level eightfold so that the membranes are in contact with an environment high in cortisol. This increased cortisol concentration may play an anti-immune role in the uterine wall, the single maternal tissue, apart from maternal blood, in direct contact with fetal tissue.

A similar relationship between corticosterone and its 11-keto analog has also been demonstrated in rodents.

Conditions of Glucocorticoid Excess

Cushing's syndrome In human Cushing's syndrome due to pituitary ACTH-secreting tumors (Cushing's disease), the morning cortisol levels are usually only minimally elevated, but the normal diurnal rhythm is lost so that the 24-h urinary cortisol, which reflects the integrated unbound cortisol level, is elevated. However the suppression of ACTH production by dexamethasone, although attenuated, is usually maintained.

In cases of ectopic ACTH-producing tumors, generally occurring in lung, cortisol levels are usually higher, and are frequently unsuppressed by dexamethasone.

Adrenal tumors cause varying levels of GCs, which are usually unresponsive to dexamethasone suppression, and are often associated with increases of adrenal androgens and/or mineralocorticoids.

Depression is common in Cushing's syndrome, and other behavioral disturbances may occur. In some cases the psychiatric features dominate over the physical features, leading to misdiagnosis. If the condition is successfully treated, either surgically or medically, the psychiatric manifestations usually subside.

Acute stress When an acute stress (threat to homeostasis) is perceived by the brain, impulses to the hypothalamus stimulate the production of CRH and VP, which, through ACTH, stimulate the production of GCs. If the stimulus is prolonged, the axis usually

adapts to it over several days, so that ACTH and GCs return to normal.

In rats, it has been shown that the response of GCs to stress in later life can be modified by neonatal handling, which appears to increase the efficiency of the stress response, and to protect the animal from potentially damaging effects of GCs.

Chronic stress Should severe stress be continued for long periods, neurodegeneration or suppressed neurogenesis in the hippocampus occurs. Similar changes also occur after 3 weeks of treatment with a high dose of GCs.

Major depression Increased levels of GCs in major depression (seen in 60–70%) are the best-documented biochemical abnormality in psychiatric disease. There is also a decrease in the diurnal variation and, in about 50%, a resistance to suppression of cortisol by dexamethasone. Major depression is twice as common in women as in men. Although CRH levels are increased, ACTH levels are not increased, so that there appears to be an alteration in adrenal responsiveness which is not understood. These changes are reversed on remission.

Conditions of Glucocorticoid Deficiency

Adrenal insufficiency (Addison's disease) In adrenal insufficiency, first described by Addison in 1855, levels of GCs are low normal or low, and respond poorly or not at all to ACTH. Insufficiency may occur due to destruction of the adrenal cortex (primary), to deficient ACTH secretion (secondary), or to deficient hypothalamic secretion of ACTH secretagogues (tertiary).

Congenital adrenal hyperplasia (genetic defects in cortisol synthesis) Inherited enzymatic defects of GCs synthesis may become manifest in fetal life, the most common being due to lack of the various enzymes involved. In order to maintain adequate GCs levels, ACTH levels are increased to overcome the block, and hypertrophy and hyperplasia of the adrenal cortex occur. Also, due to increased ACTH, synthetic steps which are not blocked produce increased quantities of their products, particularly of precursors of GCs and of adrenal androgens. While males are usually asymptomatic, the excess androgens usually cause ambiguous genitalia in female fetuses. When initially recognized, this syndrome of masculinization of female fetuses associated with enlarged adrenal glands was called the adrenogenital syndrome.

21-Hydroxylase deficiency is the most common defect accounting for 95% of all cases of congenital

adrenal hyperplasia and is particularly prevalent among the Yupik Eskimos, where the incidence is 1 in 500 births and the heterozygote frequency is 1 in 11. Milder cases of 21-hydroxylase deficiency are masculinized while more severely affected infants have the salt-losing form, causing hyponatremia, hyperkalemia, acidosis, and dehydration, sometimes leading to vascular collapse. Very mild cases may not become manifest until puberty, when hirsutism becomes prominent. If suspected, this defect can be diagnosed prenatally and treated with small doses of dexamethasone, which crosses the placental barrier (unlike cortisol, which is converted to cortisone in the placenta).

Deficiency of the following enzymes may also occur but is rare: cholesterol desmolase, 3 β -hydroxysteroid dehydrogenase/isomerase, 17-hydroxylase, and 11 β -hydroxylase.

Measurement

Competitive Protein-Binding Assays

GCs are currently usually measured by competitive protein-binding (CPB, displacement analysis). In this type of assay, the steroid is measured according to its ability to displace a tracer form of itself from a protein which binds it with high affinity and specificity. Such proteins include endogenous plasma proteins (CBGs), endogenous GR proteins, enzymes, or most commonly, antibodies raised to GCs modified to make them antigenic. The sensitivity of such methods is very great (usually a few picograms) and depends on the affinity of the steroid for the protein (usually of the order of 10^9 M⁻¹ or greater); thus for plasma only a few microliters of sample is required for the determination of cortisol or corticosterone concentrations. The specificity varies with the binding protein used, with the method of separating bound and free moieties, and with the steroid milieu in which the GCs are being measured. Since no protein is absolutely specific for any single ligand, each method must be carefully validated for the circumstances under which it is being used. The sample to be measured must be freed of any binding proteins that may interfere.

Assays Using Corticosteroid-Binding Globulin

Assays employing CBG were the first such assays to be used for GCs, and were introduced in 1963. Human CBG was the first to be used, but is less specific for cortisol than are dog or horse CBG. Each CBG has its own spectrum of specificity and can be chosen according to the milieu in which the GC is to be measured. These assays have the advantages that the binding properties of the CBG are essentially invariant, so

that it is not necessary to determine the specificity or affinity of each batch of protein; also, no preparation beyond dilution is required.

Radioreceptorassays and Radioenzymaticassays

Receptor proteins can be used to measure their ligands, and enzymes can be used to measure their substrates in similar fashion, but are not usually used for GCs.

Radioimmunoassays

Immunoassays have the important advantage that a suitable protein can be raised to virtually any steroid, and since each antibody is slightly different, the most suitable one for the milieu in which the GC is to be measured can be chosen. A disadvantage is that each batch, even from the same animal, may vary with respect to affinity and specificity and must be characterized separately to ensure consistent results. Initially it was thought that the use of monoclonal antibodies might be advantageous but the sensitivity attained is usually less than with polyclonal antibodies.

Although radioactive isotopes have been the most common labels used (hence the term radioimmunoassay), other labels are now available (see below).

Fluorescence Immunoassays

Fluorescence immunoassays employ either a fluorophore label, or utilize enzyme-immunoassays in which substrates are converted to fluorescent endproducts.

Chemiluminescence Immunoassays

Chemiluminescence immunoassays use luminescent compounds which emit light during the course of a chemical reaction, usually enzymatic. Such assays have achieved the highest levels of sensitivity to date.

Determinations in Various Body Fluids

Plasma It is important to suit the method to the purpose. For example, a method which may be adequate for the measurement of cortisol in adult human blood may be, and usually is, entirely unsuitable for its measurement in neonatal or cord blood, which contain many steroids in high concentrations (e.g., progesterone and 17-hydroxyprogesterone) that are not present or are present in only minimal amounts in nonpregnant adult blood.

Urine Similarly, such a method is rarely, if ever, adequate to measure cortisol in urine, where there are very large amounts of competing steroids, so that extra steps such as extraction and chromatography must be performed first. Although the true mean value in human urine was established in 1980 to be

about 60 nmol day⁻¹, published values continue to exceed these by a factor of 2–10 throughout the literature, so must be carefully scrutinized.

Saliva In saliva, which is convenient for the taking of samples, and more closely approximates free GCs, it must be taken into consideration that the level of cortisone (at least in humans) may exceed that of cortisol, so may interfere even with an antibody that ostensibly binds cortisone poorly. While saliva does not contain CBG, the salivary glands do contain 11 β -hydroxysteroid hydroxylase type 2, which converts about half the cortisol reaching them to cortisone, so that salivary cortisol levels are about 50% of those of unbound plasma cortisol.

Indirect Methods

Prior to the development of CPB assays, GCs were measured by indirect methods. All of these are much less specific and less sensitive than CPB methods. They include fluorescence methods (steroids with an 11-hydroxyl group fluoresce under ultraviolet light in alkali or acid), the measurement of 17-hydroxycorticoids (Porter-Silber chromogens) as an approximation of GCs, the use of tetrazolium salts to measure compounds containing an α -ketol group, 17-ketogenic steroids minus 17-ketosteroids as an approximation of GCs, ultraviolet absorption after chromatography, and double isotope dilution derivative assay.

Antiglucocorticoids

Inhibitors of steroidogenesis

A selection of inhibitors of steroidogenesis is given in [Figure 6](#).

Metyrapone mainly inhibits P450_{C11}, preventing 11-desoxycortisol from being hydroxylated at C11 to give cortisol, and 11-desoxycorticosterone from being converted to corticosterone, thereby lowering cortisol, corticosterone, and aldosterone and resulting in excessive amounts of the precursors due to stimulation of ACTH secretion.

Mitotane, which is related to the insecticide DDT (4,4'-(2,2,2-trichloroethane-1,1-diyl)bis(chlorobenzene)), is toxic to adrenal tissue, causing necrosis and hemorrhage. It also affects peripheral metabolism of cortisol, greatly increasing its conversion to 6 β -hydroxycortisol.

Aminoglutethimide affects GC synthesis in several ways: it inhibits P450_{sc}, thus decreasing the conversion of cholesterol to pregnenolone and the production of all the adrenal steroids. Although it may be useful in decreasing hypercortisolism, the blockade

Etomidate

Mifepristone (RU 486)

Figure 6 Structures of selected antiglucocorticoids.

is often overridden by increased secretion of ACTH in response to the lowered cortisol levels.

Cyanoketone inhibits 3β -hydroxysteroid dehydrogenase but it is not currently used clinically.

Ketoconazole is an antifungal agent which inhibits $P450_{\text{scc}}$ and $P450_{\text{C11}}$.

Etomidate is an anesthetic agent and its main effect is on $P450_{\text{C11}}$, although it also affects $P450_{\text{scc}}$.

Inhibitor of Glucocorticoid Receptor

Mifepristone (RU 486) inhibits GCs production by binding to the GR, and has been used successfully in some cases of Cushing's syndrome. As with agents that directly interfere with synthesis, the blockade

caused by this receptor inhibitor tends to be overcome by increased production of CRH and ACTH.

Uses of Glucocorticoids and their Inhibitors as Therapeutic Agents

Therapeutic Uses of Glucocorticoids

The first therapeutic use of GCs was that of cortisone by PS Hench and his coworkers in 1949 to treat rheumatoid arthritis. Since then, a great many disorders have been treated using a variety of GCs, including allergic diseases such as asthma and dermatitis, autoimmune diseases such as systemic lupus

erythematosis and Graves' ophthalmopathy, and inflammatory disorders such as ulcerative colitis. They have also been used to decrease cerebral edema associated with intracerebral masses, to treat septic shock, and to suppress graft rejection after transplantation of organs.

When GCs are given therapeutically, a feeling of euphoria is commonly experienced, although prolonged use often results in depression, and less often mania, especially if higher doses are used. There is no typical presentation as a variety of mental symptoms is observed, including often irritability, insomnia, obsessive-compulsive behavior, and anxiety. Altered perception, sensory flooding, delusions and hallucinations, delirium, and even frank dementia may occur in about 5% of cases. The time required for mental symptoms to occur on treatment varies from almost immediate to several months, with a median onset of 11 days. These effects are usually largely reversible after reduction of dose or discontinuation of the steroid.

Cortisone itself is inactive but it is rapidly converted to cortisol in the liver. Although the natural GCs are very effective for many purposes, if given in large amounts they have many undesirable side effects, including bloating, hypertension, peptic ulcer, trunkal obesity, osteoporosis, and depression or mania.

Since GCs have so many different biological actions, much effort has been made to develop synthetic GCs that have a particular spectrum of effects deemed desirable but lack other effects deemed undesirable (Table 1). Examples are steroids which have strong anti-inflammatory effects but lack the mineralocorticoid effects. The modification of a double bond at C1–2 as in prednisolone (or its cortisone-like 11-keto analog prednisone) increases the GC activity while reducing the mineralocorticoid activity. Addition of a fluorine atom at C9 increases both GC (about 12-fold) and mineralocorticoid (about 25-fold) activity. Including both these modifications and adding a 16 α -methyl group gives dexamethasone which has about 30-fold greater GC activity but relatively little mineralocorticoid activity. Since the steroids themselves are relatively insoluble in water, they are often formulated as organic esters such as acetates, which are somewhat more soluble, or as salts such as sodium succinates which are freely soluble.

Although extremely useful, GCs must be used with considerable caution, and preferably for only limited periods, because of their important side effects that can occur with all forms, and include bloating, osteoporosis, trunkal obesity, and other signs and symptoms of GC excess.

One of the most dangerous effects of large doses of GCs, whether natural or synthetic, is suppression of the LHPA axis. This can occur after only a few weeks of high-dose GC therapy and may require several months for recovery to occur. For this reason, therapy is never stopped abruptly but only very slowly so that the organism has time to adjust.

Uses of Antiglucocorticoids as Therapeutic Agents

Inhibitors of steroidogenesis are used to treat conditions of GC excess, including the various forms of Cushing's syndrome, and more recently, major depression. These agents may be effective for short periods, but their effects are often overcome after a few weeks or months by the normal feedback mechanism. In depressed patients, this may be long enough to induce a remission, in which case the levels remain normal after stopping the medication.

Secretion in Stress, Delivery to Target Tissues, and
Molecular Basis of Action
Functions of Glucocorticoids in Stress

Glossary

- Cell-mediated immunity* The process by which thymus-derived lymphocytes (T cells) respond to specific antigens, undergo clonal expansion, and mount a cytotoxic response.
- Humoral immunity* The process by which specific antigens activate bone marrow-derived lymphocytes (B cells), causing cell proliferation and the production and release of specific antibodies; also called antibody-mediated immunity.

Glucocorticoids are steroid hormones produced by the adrenal cortex. Their principal role is to restore homeostasis in conditions of stress. However, prolonged elevations in circulating corticosteroids, which may occur in conditions of chronic or repeated

stress, are potentially harmful and may contribute to the pathogenesis of a wide range of disorders.

Secretion in Stress, Delivery to Target Tissues, and Molecular Basis of Action

Secretion of Glucocorticoids in Stress

The glucocorticoids (GCs), cortisol and/or corticosterone, depending on the species, are produced by cells in the zona fasciculata of the adrenal cortex. In normal circumstances, serum GC concentrations are maintained within narrow limits with pronounced excursions occurring only in accord with the well-documented circadian rhythm or in response to physical or emotional stress. Circadian and stress-induced increases in GC secretion are driven by neural and humoral factors that impinge on the hypothalamus to cause the release into the hypothalamo-hypophyseal portal vessels of two neuropeptides, corticotropin releasing hormone (CRH) and arginine vasopressin (AVP); these peptides in turn act synergistically on the anterior pituitary gland to initiate the release of adrenocorticotrophic hormone (ACTH), the primary trigger of steroidogenesis. The secretion of cortisol/corticosterone is regulated further by a complex servo mechanism through which the steroids themselves negatively regulate the release of ACTH and its hypothalamic-releasing hormones. The hypothalamic-pituitary-adrenocortical (HPA) responses to repeated

or sustained stress are complex and depend on both the nature of the stress and the species. For example, in rats the adrenocortical response to cold stress is attenuated progressively with each exposure; that is, the axis becomes tolerant to the stimulus. In contrast, the HPA responses to repeated immune insults are well maintained and may become exaggerated, possibly because the feedback actions of the steroids are overcome.

Delivery of Glucocorticoids to Their Target Cells and Receptors

GCs in the systemic circulation are largely protein-bound (95%), mainly to a specific globulin, termed corticosteroid-binding globulin (CBG, or transcortin), but also to albumin. In principle, only the free steroid has ready access to the corticosteroid receptors, which are located intracellularly in the target cells. However, local mechanisms that release the steroid from its carrier protein(s) appear to exist in at least some target tissues: these include (1) interactions of the carrier protein with cell-surface CBG receptors and (2) enzymatic cleavage of CBG (e.g., by serine proteases in inflamed tissues), a process that lowers the affinity of the binding protein for the steroids. Access of the steroids to their receptors is regulated further within the target cells by 11β -hydroxysteroid dehydrogenase (11β -HSD) enzymes that control the interconversion of cortisol/corticosterone to their inactive counterparts, cortisone/ 11 -dehydrocorticosterone.

Molecular Basis of Glucocorticoid Action

The actions of the GCs are exerted mainly via the classic pathway of steroid action – the free steroid enters the target cells and binds to an intracellular receptor that is subsequently translocated to the nucleus, where it initiates specific changes in DNA transcription and, hence, in protein synthesis. In many instances, the activated steroid–receptor complex induces or represses transcription by binding directly to specific response elements in the promoter region of the gene; in others, however, it may interfere with the activity of other transcription factors, such as activator protein (AP)-1 and nuclear transcription factor (NF) κ B. In addition, the activated receptor may regulate posttranscriptional events, including mRNA transcript stability, RNA translation, and posttranslational processing of the protein.

In accord with the intracellular mode of action, the majority of biological responses to GCs are slow to emerge; some, however, are manifested more rapidly; for example, cortisol hyperpolarizes hippocampal neurons and coeliac ganglia within 1–2 min of

contact. The mechanisms underlying these rapid action are unknown, but increasing evidence favors a membrane action of the steroids, possibly via a cell surface receptor.

Corticosteroid Receptors

Two distinct subtypes of intracellular corticosteroid receptors have been identified: the mineralocorticoid receptor (MR) and the glucocorticoid receptor (GR). The MR has a high and approximately equal affinity for aldosterone and the endogenous GCs, corticosterone and cortisol ($K_d \sim 1$ – 2 nM). In contrast, the GR is of a lower affinity (K_d cortisol/corticosterone 10–20 nM), is glucocorticoid-selective, and does not bind aldosterone readily; a truncated form of this receptor, termed GR- β , which does not bind ligand but which has the capacity to bind DNA, also exists. MRs in the kidney are protected effectively from cortisol/corticosterone by type 2 11β -HSD (11β -HSD2), which acts primarily as a dehydrogenase and inactivates the steroids rapidly, thus permitting selective access of aldosterone to the receptors. MRs in the brain, however, are not always protected from GCs in this way and in many instances may be almost fully occupied at low physiological concentrations of cortisol/corticosterone. However, the delivery of GCs to GRs in organs such as the liver and white adipose tissues may be facilitated by type 1 11β -HSD (11β -HSD1), which acts primarily as a reductase and thereby regenerates the active steroids from their inactive 11 -dehydro metabolites. Although the MR undoubtedly mediates several facets of glucocorticoid activity in nonstress conditions, particularly in the central nervous system (CNS), the responses to the raised levels of the steroids observed in, for example, stress are effected primarily via GRs. These receptors are widely distributed in the body; cell responsiveness depends not only on the presence of GRs, but also the receptor concentration, which is known to fluctuate during development, the cell cycle, following disturbances in endocrine status, and on the activation of 11β -HSD1 enzymes.

Functions of Glucocorticoids in Stress

General Considerations

The concept that corticosteroids play a key role in the body's responses to stress emerged from the work of Selye on the alarm reaction and the general adaptation syndrome. It is now evident that cortisol/corticosterone displays two modes of activity. The first is a permissive or proactive role in which the steroids (1) maintain the basal activity of the HPA axis and

set its threshold for responding to stress and (2) normalize the body's response to stress by priming the body's defense mechanisms by, for example, facilitating the effects of catecholamines on lipid and carbohydrate metabolism; upregulating the expression of receptors for inflammatory mediators; and acting centrally to aid processes underlying selection attention, the integration of sensory information, and response selection. The second mode of cortisol/corticosterone action is suppressive or protective and enables the organism to cope with, adapt to, and recover from a stressful insult. Key to this mode are the powerful anti-inflammatory and immunosuppressive actions of the steroids that prevent the host defense mechanisms, which are activated by stress, from overshooting and damaging the organism. Other important protective actions include the ability of the steroids to redirect the metabolism to meet energy demands during stress, to exert important effects within the brain that promote memory processes, and to impair nonessential functions such as growth and reproductive function. The permissive actions of the steroids are evident at low physiological concentrations and are mediated at least partially, although probably not exclusively, by the high-affinity MRs. In contrast, the suppressive actions of the steroids emerge only when cortisol/corticosterone levels are raised by, for example, stress and are effected by the lower-affinity GRs.

The permissive and protective actions of GCs are complementary and enable the organism to mount an appropriate stress response and to maintain

homeostasis. Dysregulation of either by genetic or environmental factors is potentially harmful and may predispose the individual to a variety of diseases that, depending on the site of the lesion, may include depression, disorders of the host defense system, osteoporosis, obesity, diabetes mellitus, hypertension, and other cardiovascular diseases. Long-term elevations in GC production that may occur in conditions of chronic stress are particularly hazardous and may have severe deleterious effects on the body. The effects of acute and sustained elevations in serum GCs are compared in [Table 1](#).

Glucocorticoids and the Host Defense System

GCs exert multiple effects on the host defense system. In essence, they quench the early and late stages of the inflammatory response; that is, they suppress the initial vasodilation, the infiltration of leukocytes and pain, and the subsequent proliferative events associated with wound healing and tissue repair. They also oppose the changes in vascular permeability that occur in inflammation and thus reduce both edema formation and the increased permeability of the blood-brain barrier. In addition, GCs are powerful inhibitors of cell-mediated (i.e., T-cell-dependent) immune responses and may also modulate humoral (B-cell-dependent) responses. Chronic elevations in serum GCs thus induce immunosuppression and render the individual susceptible to infection.

The anti-inflammatory and immunosuppressive actions of the steroids are attributed to their powerful actions on the growth, differentiation, distribution,

Table 1 Response to acute and long-term elevations in serum glucocorticoids

<i>System</i>	<i>Acute^a</i>	<i>Long-term</i>
Host defense	Protection from potentially harmful inflammatory mediators	Immunosuppression and vulnerability to infection Poor tissue repair/wound healing
Metabolism	Mobilization of energy stores (↑ glycogen stores, ↑ gluconeogenesis, ↑ blood glucose, ↑ lipolysis, ↑ protein catabolism, ↓ peripheral glucose uptake/utilization)	Insulin-resistant steroid diabetes mellitus Centripetal obesity Protein depletion in muscle, connective, and other tissues
Musculoskeletal	Protein catabolism Altered Ca ²⁺ homeostasis	Raised serum lipids and cholesterol Impaired growth Muscle wasting Loss of connective tissue Osteoporosis and disturbed Ca ²⁺ homeostasis
Central nervous system	Improved cognitive function	Mood changes (depression and psychotic episodes) Neurodegeneration
Cardiovascular	Salt and water retention Inhibition of the production of vasoactive inflammatory mediators	Hypertension and other cardiovascular disease
Reproductive	Inhibition of hypothalamic-pituitary-gonadal function	Menstrual irregularities Infertility (male and female)
Gastrointestinal tract	Reduced bicarbonate and mucus production	Increased susceptibility to ulcers

^a↑, increased; ↓, decreased.

function, and life span of monocytes, macrophages, polymorphonuclear cells, and lymphocytes. At the cellular level, GCs reduce the number of circulating lymphocytes, monocytes, and eosinophils by causing the cells to be marginated to the lymphoid tissues, mainly the bone marrow. In contrast, blood neutrophil levels rise as the steroids prevent the cells migrating to inflamed tissues by altering the expression of adhesion proteins on their surface and on the endothelium and thereby impairing the adherence and attachment processes. The profile of circulating white cells is also influenced by the fact that GCs also induce the apoptosis (programmed cell death) of thymocytes, mature T cells, and eosinophils, although not of neutrophils.

Several processes contribute to the suppression of cell-mediated immunity invoked by the steroids. These include (1) direction of the development of undifferentiated T helper (Th) cells away from the Th1 phenotype, which is critical to cell-mediated responses, and toward the Th2 phenotype, which facilitates B-lymphocyte-dependent responses; (2) inhibition of the synthesis of interleukin (IL)-1 and IL-2 by antigen-presenting cells and T cells, respectively, and hence the impairment of antigen presentation and T-cell proliferation; and (3) induction of T-cell apoptosis. Very high levels of GCs may also depress the synthesis of the immunokines required for immunoglobulin production and, with time, decrease serum immunoglobulins. However, lesser amounts of the steroids stimulate antibody production, probably because of their positive effect on the differentiation of Th2 cells. Other immune cell functions influenced by GCs include phagocytosis and antigen processing. GCs decrease Fc receptor expression on macrophages and thus prevent the recognition of particulate antigens that are antibody-bound or optimized for subsequent clearance. They also affect mast cell and basophil function in a number of rodent models, inhibiting IgE-dependent degranulation and hence the release of histamine and leukotriene C4.

The diverse effects of GCs on immune/inflammatory cell function are explained at a biochemical level by the striking ability of the steroids to inhibit the synthesis, release, and/or activity of the army of mediators normally produced when these cells are activated. Early studies focused on the powerful inhibitory action of the steroids on the phospholipase A2 (PLA2)-dependent generation of the pro-inflammatory eicosanoids (prostanoids, leukotrienes, and epoxides) and platelet-activating factor (PAF). Several lines of evidence indicate that GCs reduce the expression of the PLA2 subtype (group II) associated with the pathogenesis of inflammation and upregulate the synthesis of

PLA2 inhibitory proteins, notably lipocortin 1 (also called annexin 1), which also influences other aspects of the inflammatory response. However, studies have shown that GCs also suppress prostanoid generation by repressing the expression of the inducible isoform of cyclooxygenase (COX II), which is normally expressed in abundance by activated monocytes, macrophages, fibroblasts, and endothelial cells.

GCs also exert profound inhibitory effects on the synthesis of many of the cytokines that are central to the manifestation of immune/inflammatory responses; these include IL-1, IL-2, IL-3, IL-6, IL-8, IL-12, granulocyte colony-stimulating factor (G-CSF), granulocyte-macrophage colony-stimulating factor (GM-CSF), interferon (IFN)- γ , tumor necrosis factor (TNF)- α , and monocyte chemotactic protein. Various mechanisms may contribute to these responses, including the downregulation of gene transcription and acceleration of mRNA degradation, together with effects at the translational and posttranslational levels. The biological actions of the cytokines may also be impaired; this may be explained in part by alterations in receptor expression and, for example, by the IL-2 receptor being downregulated by GCs. However, in many cases (e.g., IL-1, IL-6, and IFN- γ), the repression of cytokine expression is associated with the upregulation of the respective cytokine receptors ([Figure 1](#)); this phenomenon may help explain the permissive role of the steroids in priming the immune system for action as well as the ineffective responses mounted when GC levels are raised (e.g., by stress) or when adrenal function is impaired.

The release of many other inflammatory mediators may also be prevented by virtue of the powerful regulatory actions of the GCs on the enzymes responsible for their biosynthesis/degradation. For example, GCs suppress the inducible form of nitric oxide (NO) synthase and hence the generation of NO by macrophages. However, they promote the metabolism of nonlipid inflammatory mediators (e.g., bradykinin) by upregulating the enzymes responsible for their metabolism. Further important actions of the GCs include reductions in the serum complement components, in the release of mediators such as 5-hydroxytryptamine (5-HT), and in the production/activity of the proteolytic enzymes (e.g., elastase and collagenase) that are concerned with the late stages of inflammation.

Metabolic Actions of Glucocorticoids

GCs exert complex effects on carbohydrate, lipid, and protein metabolism; their principal actions are catabolic, and they thus mobilize energy stores and oppose the actions of insulin ([Figure 2](#)).

Figure 1 Mathematical model for the permissive and suppressive effects of glucocorticoids over a physiological concentration range. (a), Dose–response curves for a theoretical mediator and its specific receptors; (b), mathematical composite of mediator–receptor complex formation indicating biological activity and suggesting a mechanism by which low cortisol levels could be permissive and stress-induced cortisol surges suppressive in effect. From Munck, A. and Náraj-Fejes-Tóth, A. (1992), The ups and downs of glucocorticoid physiology: permissive and suppressive effects revisited, *Molecular and Cellular Endocrinology* **90**, C1–C4, copyright John Wiley & Sons Limited. Reproduced with permission.

Carbohydrate metabolism

The principal target is the liver, where GCs increase glycogen storage and gluconeogenesis. The effects of the steroids on glycogen storage reflect an increase in glycogen deposition due to the activation (dephosphorylation) of glycogen synthase and a concomitant decrease in glycogen breakdown due to inactivation of the glycogen-mobilizing enzyme glycogen phosphorylase. The increase in glucose synthesis is explained partly by the upregulation of key enzymes in the gluconeogenic pathway, such as phosphoenolpyruvate carboxykinase (PEPCK). In addition, the catabolic effects of the steroids on protein metabolism in peripheral tissues (e.g., muscle) and lipolysis in adipose tissue increase the availability of substrates (glucogenic amino acids and glycerol), while the fatty acids released with glycerol provide an important energy source for the process. The actions of GCs in the

Figure 2 Schematic diagram illustrating the effects of glucocorticoids on carbohydrate, protein, and lipid metabolism. Note that the positive effects of the steroids on lipolysis involve interactions with other lipolytic agents (e.g., growth hormone and catecholamines). ⊕, stimulation; ⊖, inhibition; AA, amino acid; FFA, free fatty acid; GT, glucose transporter.

liver are effected by GR, and the delivery of the steroids to the receptors is facilitated by an abundance of 11 β -HSD1, which serves mainly as a reductase.

Although much of the glucose formed in the liver in response to GCs is stored locally as glycogen, some is released into the circulation. Blood sugar levels are enhanced further by the actions of GCs in the peripheral tissues, which lead to the downregulation of the glucose transporters and, hence, to decreased glucose uptake and use.

Lipid metabolism GCs exert a permissive influence on lipid metabolism, producing an acute lipolytic action that appears to reflect an increased responsiveness to catecholamines, growth hormone (GH), and possibly other lipid-mobilizing agents. In the long term, however, GCs produce a striking redistribution of fat, with enhanced deposition in the trunk (centripetal obesity), dorsocervical and subcapsular regions (buffalo hump), and face (moon face), together with a loss of fat in the upper and lower limbs, giving rise to the 'lemon-on-sticks' appearance that is exacerbated by the changes in protein metabolism. Blood lipid and cholesterol levels are also raised. The underlying mechanisms are poorly defined; they may

involve alterations in insulin secretion triggered by the changes in glucose homeostasis, and it is interesting to note that white adipose tissue is rich in GRs and 11 β -HSD1. Paradoxically, this pattern of fat redistribution is not seen in experimental animals.

Protein metabolism GCs have a powerfully catabolic effect on protein in muscle and other tissues with the consequent release of amino acids into the circulation, which are converted to glucose in the liver. Long-term elevations in serum GCs may cause severe muscle wasting.

Skeleton and Connective Tissue

Skeleton GCs exert direct and indirect effects on bone, and persistent elevations of serum GCs may lead to osteoporosis. The steroids decrease bone formation by inhibiting (1) the proliferation and differentiation of osteoclasts and (2) the production of type 1 collagen, osteocalcin, and other matrix components such as mucopolysaccharides and sulfate glucoaminoglycans while increasing the expression of collagen. In addition, they exert complex effects on the expression of growth factors and their receptors and reduce Ca^{2+} stores by decreasing intestinal Ca^{2+} absorption, increasing renal Ca^{2+} excretion, and raising serum parathyroid hormone (PTH) levels. GCs also promote bone resorption through mechanisms that are secondary to the rise in PTH and possibly also via direct actions on the bone.

Sustained elevations in serum GCs inhibit linear growth in children and experimental animals. The mechanisms responsible have yet to be defined but are likely to reflect the actions of the steroids on the bone, principally at the site of the epiphyses. Although there are reports to the contrary, the majority of data suggests that the serum levels of GH, insulin-like growth factor (IGF)-1, and IGF-binding proteins are normal in these subjects.

Connective tissue The actions of GCs on connective tissue lead to poor wound healing and tissue repair. The steroids decrease fibroblast proliferation and function; inhibit the production of the matrix proteins, collagen, and hyaluronidate; and augment the production of the matrix-degrading enzymes collagenase, elastase, and hyaluronidase. However, GCs augment the production of fibronectin, a matrix glycoprotein.

Cardiovascular

Elevations in serum GCs raise blood pressure. This may be at least partially explained by mineralocorticoid-like actions of the steroids, which cause increased

salt and water retention, and by the anti-inflammatory actions of the steroids, which prevent the release of local vasodilator substances such as prostacyclin and bradykinin. However, other mechanisms also come into play. These include (1) the upregulation of vascular α_1 -adrenoceptors and consequent increased sensitivity of the vessels to the vasoconstrictor actions of norepinephrine; (2) increased cardiac output, possibly as a result of increased β_1 -adrenoceptor expression in the myocardium; and (3) increased production of angiotensinogen and increased sensitivity of the blood vessels to the vasoconstrictor actions of angiotensin II. The endothelium is rich in GRs, and it is conceivable that the steroids also modulate the release/activity of other locally produced vasoactive substances. In addition, reports that GRs are abundant in the brain-stem nuclei raise the possibility that GCs may also act centrally to alter sympathetic outflow.

Mood and Behavior

GCs released in stress may exert significant effects on cognitive function, mood and behavior, and reception of sensory inputs. Subjects whose serum GCs are raised due to either Cushing's disease or exogenous steroids also show marked disturbances in sleep, with a reduction in time spent in the rapid eye movement phase.

Studies on laboratory animals have shown that GCs act in the neocortex and limbic system (hippocampus, septum, and amygdala) to modify learning and memory processes in a context-dependent manner. Thus, an acute rise in GCs may facilitate learning and memory processes but also eliminate learned behavior that is no longer of relevance. The complex actions of the steroids involve both MRs and GRs, with MRs effecting the appraisal of information and response selection and GRs promoting the processes underlying the consolidation of acquired information. The long-term effects of GCs on learning and memory are less well researched and the data available are conflicting, although, when given with neurotoxic agents, learned behavior is impaired by the steroids.

GC levels are raised in some patients with depression, but it remains to be determined whether this is cause or effect; indeed, the effects of GCs on mood appear variable. Thus, approximately one-half of patients with iatrogenic or endogenous Cushing's disease show psychological disturbances; depression is the most common but some subjects show euphoric or manic behavior and, in some cases, overt psychoses. Patients with adrenal insufficiency also frequently experience mood changes; paradoxically, the most common is also depression.

Increasing evidence suggests that sustained elevations in serum GCs, such as those that occur due to chronic stress, may contribute to the processes of neurodegeneration. The toxic actions of the steroids, which have been studied most widely in the hippocampus, are associated with altered glutaminergic transmission, a long-term enhancement of Ca^{2+} influx, and depletion of ATP stores, with a consequent impairment of essential energy-requiring processes such as glucose uptake. The vulnerability of the neurons may be enhanced further by a reduction in neurotrophic capacity because the elevations in serum GCs induced by chronic stress or the administration of exogenous steroids inhibit the expression of brain-derived neurotrophic factor mRNA and also tyrosine kinase, which is required for growth factor action.

Reproductive Function

GCs act at multiple sites within the hypothalamic-pituitary-gonadal axis to impair reproductive function; hence, chronic elevations in serum GCs lead to infertility and menstrual irregularities. An important site of action of the steroids is the hypothalamus. In addition, the steroids exert significant effects at the pituitary level to depress gonadotropin-releasing hormone (GnRH)-driven gonadotropin release and may also exert further regulatory actions within the gonads.

Development

GCs exert both positive and negative effects on cell growth. In addition, they fulfill complex organizational effects pre- and postnatally and thus play a key role in developmental programming. Not surprisingly, the HPA axis is tightly regulated during perinatal life and, in rodents, the stress response is attenuated during a critical phase postnatally. At this time, the developing HPA axis shows a high degree of plasticity, and a growing body of evidence suggests that disturbances in the GC milieu may (1) trigger a plethora of pathologies (e.g., growth retardation or impairment of CNS development) and (2) precipitate abnormalities in GC secretion that persist into adult life and may increase the susceptibility of the individual to conditions as diverse as hypertension, insulin resistance, cognitive and other behavioral disorders, and allergic/inflammatory disease. Perinatal manipulations that alter the expression of GRs (but not MRs) in the brain are particularly hazardous in this regard because, by disrupting the negative feedback mechanisms, they alter the responsiveness of the HPA axis to stress throughout the lifetime of the individual. For example, the exposure of neonatal rats to stimuli that raise serum GCs, such as

an immune insult (the injection of bacterial lipopolysaccharide) or the administration of exogenous GCs, results in the adult in the downregulation of GRs in the hippocampus and hypothalamus, decreased sensitivity of the HPA axis to the negative feedback actions of the GCs, and exaggerated HPA responses to stress. Similar long-term changes in GR expression occur in rats subjected to prolonged periods of maternal separation; the consequent impairment of the negative feedback system and changes in HPA function are associated with alterations in T-cell antibody responses and in the incidence of age-related neuropathies. In contrast, neonatal handling, which increases hippocampal GR expression by mechanisms involving serotonin, reduces the magnitude and duration of the stress response in the adult; maternal care may therefore help to program events that regulate responses to stress in the adult and thus reduce vulnerability to disease.

Other Actions

GCs inhibit the production of mucus and bicarbonate in the stomach and small intestine by virtue of their ability to block prostaglandin production; sustained elevations in GCs thus increase susceptibility to gastric and duodenal ulcer formation. The steroids also promote Na^+ absorption in the colon by mechanisms that involve MRs and GRs while acting via GRs to augment Na^+ excretion by stimulating the synthesis of atrial natriuretic peptide (ANP) and augmenting the actions of ANP on the kidney, thereby opposing the Na^+ -retaining influence exerted via MRs in the distal renal tubule. In addition, GCs may enhance free-water clearance by depressing the synthesis of vasopressin.

Summary

Glossary

<i>ATP/ADP</i>	Ratio of adenosine triphosphate to adenosine diphosphate, an index of cellular energy stores.
<i>Dinitrophenol</i>	A mitochondrial inhibitor associated with increased glucose transport <i>in vitro</i> .
<i>GLUT</i>	Glucose transport proteins enumerated in the order of their cloning, e.g., GLUT1, GLUT2.
<i>Mitogen-activated protein kinase</i>	A family of enzymes activated by hormones, cytokines, stress, and growth factors that result in a cascade of kinase activity and thereby influence cellular signaling.

Introduction

Glucose transport supplies fuel needed for energy metabolism by all mammalian cells. The supply of glucose is particularly important for cells, such as the neurons of the brain, that have a high metabolic rate supported by an obligate consumption of glucose as fuel. Transport is regulated by a variety of factors, including those associated with stress. The transport proteins that accomplish glucose transport are modulated in their expression, cellular distribution, synthesis, and half-lives by stress-related factors. Such factors include stress hormones, metabolic stress such as cellular energy demand or reduced supply of fuel or oxygen, and stress-related kinase signaling. The net effect of such regulation may be to ensure appropriate distribution of glucose fuel during stress to tissues that most require this particular fuel.

Glucose Transport

Simple diffusion of glucose across cellular phospholipid barriers is limited by its modest hydrophobicity. To overcome this, transfer of glucose across cell membranes uses a process known as facilitated diffusion, which is a carrier protein-mediated process. Two types of facilitated diffusion exist: energy dependent and energy independent. A few cells, such as the gut and kidney epithelium, are directly energy dependent and use a sodium-glucose cotransport. For most cells, however, energy-independent facilitated diffusion predominates. Facilitated diffusion via carrier proteins transports glucose down a concentration

gradient in a saturable manner and is the major mechanism for glucose entry into mammalian cells. Such transport is accomplished by different isoforms of a superfamily of hydrophobic, integral membrane proteins often referred to as GLUTs or glucose transporters (see [Figure 1](#)). The cloning of the first member of this family, GLUT1, has facilitated much of the physiological investigation of glucose transport and these proteins. The homology of these transporters has led to additional members of this family of proteins being

Figure 1 A model of glucose transporters. The diagram illustrates the putative 12 membrane-spanning domains of the glucose transporter's proposed structure, based on its cloning by Mueckler. This structure is reproduced for all class I GLUTs but is slightly different in placement of the carbohydrate moiety on the exofacial loop in other GLUT types. In this model of GLUT1, an N-linked asparagine residue on the exofacial (upper) surface of the cell membrane has an attached carbohydrate moiety that in certain isoforms may alter the efficiency of transport function. N- and C-termini of the proteins reside in intracellular sites.

identified. Their characterization physiologically in relation to stress signaling is as yet incomplete. [Table 1](#) lists the members of the GLUT family (excluding HMIT) of proteins and partially characterizes them. In brief, the GLUT family of transporters of hexoses and polyols now has 13 members, including 12 hexose transporters and one myoinositol transporter (HMIT). There are three classes within the transporter family: class I includes GLUT1–4, class II includes GLUTs 6, 8, 10, and 12, and class III includes 5, 7, 9, 11, and HMIT.

Overview of Glucose Transport Regulation

Glucose transport is a highly regulated process that varies considerably from one cell type to another. Some cells, such as red blood cells and brain neurons, have obligate consumption of glucose. For other cells, a facultative use of glucose exists, permitting other metabolic fuels, such as fatty acids, to supply the bulk of local energy requirements. Much evidence suggests that the regulation of glucose transport is also isoform specific. Regulation of transport occurs in response to altered energy requirements of tissues, so it is not surprising that one form of cellular stress, energy lack, is a potent regulator of glucose transport and transporter expression by different tissues. Regulation of GLUT proteins may occur by variation of the amounts of synthesis or degradation of the GLUT protein or mRNA. An increased transcription of GLUT mRNA or other regulatory effects on GLUTs

Table 1 The GLUT family (SLC2), with each member (except the related SMIT myoinositol transporter) listed and given its class, and some characteristics of tissue distribution and other features.

Common name	Class	Tissue distribution	Features/Comments
GLUT1	I	Brain microvessels, glia, erythrocytes, placenta, kidney	Widely expressed, synthesis induced by cell culture, growth factors, oncogenes, heat shock, cell stress, development
GLUT2	I	Liver, kidney, pancreatic β cells, small intestine	Low-affinity (high K_m) transporter, role in insulin release
GLUT3	I	Neurons, placenta, fetal skeletal muscle, platelets, leukocytes	High affinity (low K_m), expressed in glucose-dependent cells, regulated by development, metabolic stress
GLUT4	I	Skeletal muscle, heart, brain regions, vessels	Insulin responsive, translocates from intra-cellular compartment to plasma membrane stress hormone modulation
GLUT5	II	Testes, small intestine,	High affinity (low K_m) for fructose
GLUT6	II	Brain, spleen, leukocytes	Function ill defined, formerly GLUT9
GLUT7	III	Unknown	Homologous to GLUT5,? fructose transporter
GLUT8	II	Testes, brain, adrenal, liver spleen, fat, lung, blastocyst	High affinity for glucose, hormone/stress modulation
GLUT9	III	Kidney, liver	Transport activity unclear, GLUT5 homology
GLUT10	II	Heart, lung, brain, liver	High 2DG affinity
GLUT11	III	Liver, brain, lung, muscle	Low glucose affinity, multiple splice variants
GLUT12	II	Heart, muscle, fat, prostate	Substrate specificity not known

may occur as a result of stress hormones, such as glucocorticoids and epinephrine. In some tissues, these hormones have differing effects on expression of GLUTs or their transport activity, emphasizing their tissue-specific regulation. The effects of growth factors, physiological factors often involved in stress responses, increase GLUT1 transcription.

Stress Hormones and Glucose Transport

Stress hormone responses influence glucose transport in a tissue-specific and isoform-specific manner. Among the important influences on glucose transport are the stress hormones, particularly adrenal glucocorticoids. Another common stress hormone response that regulates glucose transport is the secretion of catecholamines, epinephrine and norepinephrine, by the adrenal medulla and the sympathetic nervous system. Glucocorticoid stress responses or exposure to synthetic glucocorticoid drugs, such as dexamethasone, regulates the expression of several glucose transporter isoforms. In cultured adipocytes and in skeletal muscle, which are both insulin-sensitive tissues, glucocorticoids downregulate glucose transport by decreasing the plasma membrane concentration of glucose transporters, particularly GLUT4, the insulin-sensitive glucose transporter. This was shown by several groups. This cellular redistribution of GLUT4 is opposite to the effects of insulin.

Kinase signaling may be important for glucose transport adaptations in response to stress hormones. In 3T3-L1 adipocytes, downregulation of GLUT4 activity has been found. The alteration is not from decreased PI3 kinase signaling, as might be expected, nor is it from downstream regulation in this insulin-responsive pathway. Instead, a decrease in p38 mitogen-activated protein (MAP) kinase phosphorylation occurs. This is caused by upregulation of MAP kinase phosphatases.

In adipocytes, glucocorticoids may stimulate the synthesis of GLUT1, however, consistent with tissue and isoform specificity of regulation. GLUT1 is also overexpressed in the small blood vessels of the brain (which comprise the blood-brain barrier) after *in vivo* dexamethasone treatment. β -adrenergic drugs and the stress hormone catecholamines may also reduce insulin-sensitive glucose transport via action of GLUT4 in tissues such as muscle and fat, although precise mechanisms are incompletely defined.

In the gut, GLUT2 may be downregulated as a result of stress. A complex effect of stress (restraint stress and uncontrolled diabetes have been studied) is seen with GLUT8 in the hippocampus. Short-term

stress had no effect alone but normalized the increased GLUT8 mRNA levels resulting from diabetes. The GLUT8 protein shows no change in total protein, but instead a redistribution induced by stress in GLUT8 protein to high-density microsomal fractions occurs. Intriguingly, both uncontrolled diabetes and restraint stress lower GLUT8 protein in high-density microsomes, and the two combined reduce levels to a greater degree than either alone. These examples of stress hormone-mediated effects on glucose transport suggest the importance of tissue, stress, and isoform specificity when understanding the effects of stress on glucose transport. The net effect of such regulation may redistribute glucose to tissues such as the brain that most need it as a fuel. Tissues, such as muscle, during stress may utilize other fuels, e.g., fatty acids. Some of these stress responses are thus thought to be adaptive, although given the biphasic nature of some, there may also be maladaptive or deleterious aspects, particularly of combined stresses.

GLUT1 as a Stress-Related Protein

GLUT1, the ubiquitously expressed glucose transporter, which is constitutively expressed at low levels by most, if not all, cells, is regulated by cellular stress. A variety of cell stressors, including glucose starvation, mercaptoethanol, calcium ionophores, tunicamycin, and heat shock, upregulated glucose transport and GLUT1 expression in L8 muscle cells and in 3T3L1 fibroblasts in an isoform-specific fashion. Another glucose transporter, GLUT4, failed to respond similarly. The GLUT1 stress responses were regulated in a manner very similar to that seen for another cell stress protein, glucose-regulated protein 78 (GRP78), in these studies. Subsequently, other studies confirmed the stress-related increase in GLUT1 expression in a variety of tissues and cell types. GLUT1 is thus the prototypical stress-responsive GLUT isoform. Nonetheless, many other GLUT isoforms are regulatable by factors associated with stress.

Metabolic Stress and Glucose Transport

Hypermetabolism

One aspect seen frequently with cellular stress or injury is a transient hypermetabolism. Perhaps this hypermetabolism is used to provide biochemical energy in the form of ATP or its high-energy phosphate bond equivalents for restoration of ionic cellular equilibrium and energy-dependent repair processes. The increased energy requirements after stress or

injury might exert regulatory effects on glucose transport and transporters through an energy intermediate in the metabolic pathways of glucose. A potential linkage to altered metabolism and glucose transport is the fuel sensor enzyme AMP kinase, which accelerates catabolic pathways such as glycolysis and fatty acid oxidation to restore the ATP/AMP ratio that may be depleted. Increased glucose transport can be seen in some tissues as a result of AMP kinase activation.

Mitochondrial Inhibitors

Metabolic stress may regulate glucose transport and transporters *in vivo* and *in vitro*. Inhibitors of mitochondrial oxidative phosphorylation have long been known to increase glucose transport *in vitro*, although the precise metabolic pathways and mechanisms are complex and only partly elucidated. This phenomenon was first described in cultured fibroblasts. Mitochondrial inhibitors may similarly affect GLUT proteins. Hypoxia and mitochondrial inhibitors or uncouplers of oxidative phosphorylation (dinitrophenol, antimycin, and azide) act similarly to hypoxia and increase both GLUT1 mRNA and protein expression *in vitro*. Increasing evidence supports the idea that GLUT3 may also respond to these stimuli, albeit through different mechanisms than GLUT1 or GLUT4.

Fuel Deprivation: Oxygen, Glucose, Ischemia

In a like manner, glucose transport is upregulated by fuel deprivation *in vitro* and *in vivo*. This deprivation may occur due to glucose lack, hypoxic conditions, or ischemia. Glucose deprivation induced upregulation of glucose transport has been shown in fibroblasts, in muscle cells, and in many other cell types. Some forms of feedback probably occur by metabolic intermediates in the metabolism of glucose and/or by feedback directly from the energy state of the cell, although the specific metabolic compound is not clear. Perhaps ATP levels or ATP/ADP ratios may be involved in mediating this increased glucose transport. Indeed, a substantial body of evidence suggests that the regulation of glucose transport in many tissues is influenced by the availability of the transport substrate itself, i.e., glucose. Altered blood flow, reduced oxygen, or glucose availability may increase transport. Hypoxia and hypoglycemia can exert their effects on glucose transport (GLUT1) at least partly through action of vascular endothelial growth factor (VEGF). In some situations this occurs through extension of the half-life of the mRNA for VEGF. Hypoxia and ischemia may also induce hypoxia-inducible factor 1 alpha (HIF-1 α), which in turn may be involved in

upregulation also through AMP kinase, the previously mentioned fuel sensor enzyme.

Overall Effects of Transport Regulation

The net effect of GLUT regulation in stress is to redistribute glucose fuel to tissues that have an obligate requirement for this energy substrate. Glucocorticoids may upregulate GLUT1 protein expression in tissues such as the brain, resulting in increased availability of fuel for that tissue. A complex aspect of that upregulation, however, is that endothelial cells may also have a relatively acute effect to decrease transport activity of glucose as well, leaving the net effect to vary depending upon the balance of transport-inhibiting effects that are probably not related to GLUT expression and enhancing effects that probably are related to GLUT expression. In contrast to effects in the brain of glucocorticoids, in insulin-dependent tissues, which employ GLUT4 as their primary glucose transporter, an intracellular sequestration of this transporter may prevent draining of glucose fuel by muscle during stress responses.

Although there is controversy about this point in some tissues, evidence suggests that local energy metabolism may be affected by such stress-mediated regulation of glucose transporters and glucose transport. For example, with *in vivo* hypoglycemia, an upregulation of brain endothelial transport of glucose occurs in animal studies and in some human studies. At blood glucose levels of about 3 mM (equal to 56 mg/dl), brain dysfunction normally begins to occur and presumably is related to a lack of adequate glucose entry into the brain to support the rather rigid requirement for glucose by brain metabolism. With an adaptation of glucose transport that occurs within several days of repeated hypoglycemia (in this case produced *in vivo* by overdoses of exogenous insulin), there is maintenance of glucose-6-phosphate and brain creatine phosphate and ATP levels. Presumably, the increased transport efficiency, which appears to involve both brain vascular (GLUT1) and neuronal glucose transporters (GLUT3), effectively operates to shuttle a greater amount of glucose across the brain endothelial and neuronal cellular barriers. This helps feed starving neurons. Interestingly, although such an adaptation would seem to be an unalloyed benefit, it has been suggested that a reduced awareness of hypoglycemia also occurs as a result. This reduced awareness may actually increase the risk of subsequent hypoglycemia in those with insulin-treated diabetes, which might risk brain injury from fuel deprivation. Glucose sensing in the brain may occur in discrete

neurons, which may be important in hypoglycemia responses and in feeding.

Signaling Cascades and Glucose Transport

Stress in cells and whole organisms is associated with a wide variety of hormonal and biochemical changes that induce cellular responses via many mechanisms. One mechanism for signal transduction in stress occurs via certain types of MAP kinase pathways, particularly the p38 and jun-kinase subtypes. The p38 kinases, mammalian homologs of osmotic stress kinases found in yeast, may help regulate both basal- and stress-activated expression of glucose transporters, including GLUT1 and GLUT3, according to work performed in cultured muscle cells. The fuel sensor kinase, AMP kinase, is able to stimulate GLUT expression in some tissues as well.

Summary

It is clear that stress can either activate or suppress glucose transport in many tissues. GLUT1, the widely expressed isoform, appears to be a prototype of the stress-activated glucose transporter isoform, but GLUT3 and GLUT4 may also increase or decrease in response to certain kinds of cellular stress. New data suggest that GLUT2 and GLUT8 show stress-related regulation as well. Less is known about the regulation of other GLUT isoforms. Hormones associated with stress response may be important for increasing or, in some instances, decreasing cellular glucose transport. The preservation of an adequate supply of glucose fuel to tissues is believed to be adaptive, but occasionally the redirection of glucose to certain tissues may also have adverse consequences. Adaptations of glucose transport and GLUT transporters are responsive to many signaling pathways activated by stress, including hormones, kinase signaling, fuel or oxygen or energy lack, and probably other pathways as yet incompletely delineated. Stress-mediated changes in glucose transporter amount or function probably act to redistribute this fuel to tissues such as the brain that have an obligate demand for it.

Glycoconjugates Are Important Mediators of Many Physiological Functions

Glycoproteins in Stress

Lectins in Stress

Stress Affects the Activity of Glycosyltransferases

Model of Glycobiology of Stress

Glossary

<i>Glyco-conjugate</i>	A compound composed of an oligosaccharide linked to a protein or a lipid.
<i>Glycolipid</i>	A compound containing both lipid and oligosaccharide moieties.
<i>Glycoprotein</i>	A protein molecule containing one or more oligosaccharide attachments.
<i>Glycosylation</i>	The posttranslational modification of a protein by the addition of a carbohydrate moiety; catalyzed by specific enzymes called glycosyltransferases.
<i>Glycosyl-transferase (GT)</i>	A group of enzymes that transfer monosaccharides to a growing oligosaccharide chain on glycoconjugates.
<i>Lectin</i>	A physiological receptor for carbohydrate structures attached to glycoconjugates.

Sialyltransferase

An enzyme that transfers sialic acid to a glycoconjugate.

The metabolic response to psychological stress is a very complex and demanding physiological process that involves numerous organs and organ systems. Although it is highly important for survival in an ever-changing environment, its excessive activation is associated with various detrimental effects. A number of epidemiological and experimental studies conducted during the past years have clearly demonstrated a link between stress and the development and course of many diseases, from simple virus infections and gastric ulcers to cardiovascular diseases and cancer. It is estimated that up to two-thirds of all visits to the physician's office are associated with stress.

Molecular mechanisms underlying the link between the response to stress and the development of disease appear to be exceedingly complex and are only partly understood. Although hormonal changes are key mediators of the physiological changes in stress, other factors appear to be decisive in the development of stress-associated disorders. Molecular response of a target cell appears to be defined not only by the incoming hormone but also by the current molecular situation within the cell itself. A good illustration of this principle is the way in which corticosteroids affect neurons in the hippocampus. If neurons are at rest, corticosteroids apparently have no effects. These effects become visible only when neurons are shifted from their basal condition by the action of neurotransmitters.

After more than 50 years of research, a lot is known about the endocrinology of the stress response, but the key molecular mechanism that explains how and why corticosteroids and other stress hormones cease to be beneficial and start to cause damage is still not known. One important link between stress and disease is the stress-induced decrease in the immune response, but the decrease in the immune response cannot explain all the effects of stress and other mechanisms have to be involved. Glycosylation appears to be involved, and the modification of glycoconjugate structures and their interaction with lectin receptors modulate at least some of these processes.

Glycoconjugates Are Important Mediators of Many Physiological Functions

Glycosylation is a very complex posttranslational modification that plays an important role in the integration of higher organisms. The surface of all cells is covered by oligosaccharide structures covalently attached to proteins and lipids (glycoproteins and glycolipids). Escalation in the extent and diversity of protein glycosylation correlates with the appearance of multicellular life, and apparently most of the interaction between cells and their surroundings include carbohydrate–protein recognition. An essential difference between proteins and the oligosaccharide structures attached to them is the fact that the carbohydrate part is not encoded in the DNA (Figure 1). Although genes unequivocally define the structure of each protein, there is no template for attached oligosaccharides. This makes them inherently sensitive to all changes within the cell, and glycan structures that are being produced at any individual moment actually mirror all relevant past events in the cell. In addition, the evolution of carbohydrate structures is much faster than the evolution of proteins, and often in different species we see significant differences in carbohydrate structures attached to nearly identical protein or lipid backbones.

Glycan parts of glycoconjugates are being synthesized by GTs that act in a sequence, and each

enzyme transfers specific monosaccharide to a specific acceptor contributing to the final glycan structure (Figure 2). It is estimated that over 300 specific enzymes (glycosidases and GTs) are involved in the synthesis of carbohydrate structures on glycoconjugates, and the whole process is very complex and energy expensive for the cell. Defects that disturb early phases of glycoconjugate synthesis are incompatible with multicellular life, whereas mutations in the end modifications of oligosaccharides result in specific physiological alterations. Because oligosaccharide structures are not encoded in genes, the final structure of a glycan is determined by the current cellular repertoire of expressed GTs (the expression, intracellular localization, and regulation of specific GTs that is commonly referred to as the glycosylation phenotype).

At the level of the individual molecule, from the structural point of view, there is no significant difference between the protein and carbohydrate parts. Glycoprotein is an entity composed of a protein and a carbohydrate part, and both parts have structural and functional roles that are specific to a given protein. Due to very high structural variability and the lack of adequate methods to analyze them, the carbohydrate parts of glycoconjugates were ignored by the most of the scientific community until very recently. However, thanks to the development of novel methods, in the last decade there has been an exponential increase in the knowledge about the physiological roles of carbohydrate structures. Now it is known that glycan part of glycoconjugates are crucial for many physiological processes from fertilization and development to regulation of hormonal activity and the formation of memory. Recent evidence has established differential glycan processing as a novel regulator of protein function, and the speculation that the invention of glycosylation was the key evolutionary step that enabled the development of multicellular organisms appears to be correct.

Figure 1 Central dogma of molecular biology amended with the biosynthesis of glycoproteins. Contrary to proteins, which all have their templates in the DNA, the carbohydrate structures attached to glycoproteins are not defined by genes. Their exact structures are determined by the regulation of expression, intracellular localization, and activity of various glycosyltransferases.

Figure 2 Schematic representation of processing of N-linked glycans. N-linked glycans are being synthesized by sequential action of numerous glycosyltransferases and glycosidases that add or remove specific monosaccharides to a growing oligosaccharide chain.

Glycoproteins in Stress

The influence of stress on glycosylation was first studied on gastric mucosa in rats. Mucosal cells of rats stressed by immersion in water were found to incorporate up to 50% less N-acetylgalactosamine than control animals. Subsequently, it was also shown that stress is associated with changes in the binding of lectins to gastric mucosa. Stress-induced alterations were found in the binding of several lectins, the most specific being changes detected with peanut agglutinin (PNA) lectin that specifically recognizes galactose $\beta(1,3)$ linked to N-acetylgalactosamine. These studies were not continued, but they undoubtedly indicated that stress does have some influence on glycosylation. *Helicobacter pylori* (causative agent of most peptic ulcers) attaches to the gastric mucosa through specific interactions with carbohydrate structures, and the stress-induced changes in the expression of these structures might be one of the molecular mechanisms that explains the effects of stress on the development of gastric ulcers.

An indirect confirmation of the hypothesis that structures of glycoconjugates might change in stress came from the studies of acute-phase proteins in depression. For some time, it is known that depression can significantly influence the immune system, especially some positive acute-phase proteins such as haptoglobin or α_1 -acid glycoprotein. Similar changes were detected in association with surgical stress, and recently it was shown that even a single episode of uncontrollable stress can activate acute-phase response in the experimental animals. Nearly all acute-phase proteins are glycosylated, and in addition to changes in the concentration of the whole proteins, depression is also associated with changes in the individual carbohydrate structures attached to acute-phase proteins. Specific changes in carbohydrate structures on glycoproteins also occur during inflammation and some diseases that are associated with stress. In their recent work, van Dijk and colleagues proposed that these changes might be associated with the regulation of the immune response.

The first indications that psychological stress can influence human glycoconjugates came from the studies of Flögel and colleagues in early 1990s. They used lectin-western blot to analyze changes in the glycosylation of proteins in sera of prisoners released from the Serbian concentration camps during the war in Croatia and Bosnia. Significant changes in glycosylation patterns were established with several different lectins, each recognizing specific segments of the oligosaccharide structure (Table 1).

Corticotropin releasing hormone (CRH) plays a crucial role in integrating the body's overall response

Table 1 Specificity of lectins^a

Lectin	Source	Specificity
GNA	<i>Galanthus nivalis</i>	Man- $\alpha(1,3)$, Man- $\alpha(1,6)$; Man- $\alpha(1,2)$ -Man
SNA	<i>Sambucus nigra</i>	Sia- $\alpha(2,6)$ -Gal
MAA	<i>Maackia amurensis</i>	Sia- $\alpha(2,3)$ -Gal
PNA	Peanut	Gal- $\beta(1,3)$ -GalNAc
DSA	<i>Datura stramonium</i>	Gal- $\beta(1,4)$ -GlcNAc

^aLectins are physiological receptors for carbohydrate structures in animals and plants. Plant lectins are easy to isolate and they are commercially available as tools for specific recognition of the exactly defined segments of carbohydrate structures.

to stress, including the integration of the response of the immune system to physiological, psychological, and immunological stressors. In addition to the hypothalamus, where it was initially identified, CRH, its receptors, and related ligands are present throughout the brain and periphery. By activating the glucocorticoid and catecholamine secretion, CRH from the central nervous system (CNS) mediates the suppressive effects of stress on the immune system. The action of CRH is exhibited through CRH receptors CRH1 and CRH2, which are differentially expressed on brain neurons located in neocortical, limbic, and brainstem regions of the CNS and on the pituitary corticotrophs. An intriguing aspect of both CRH receptors and CRH binding protein is their glycosylation pattern. CRH1 contains five potential N-glycosylation sites. Early studies showed that its glycosylation differs in different regions of the CNS, indicating potential functional roles for different glycoforms. The conversion of oligosaccharide chains to oligomannose structures by kifunensine (an inhibitor of mannosidase I that prevents the conversion of oligomannose to complex glycans) was reported not to change the ligand-binding properties of individual receptors, but mutation experiments have shown that the presence of at least three (out of five) oligosaccharide chains is required for normal CRH1 function.

Another system in which glycosylation might play an important role in the stress response is the cholinergic activation of the brain. It is generally accepted that in the CNS stress induces primarily cholinergic hyperactivation. Within several hours, the excess acetylcholinesterase (AChE) exerts a protective effect by retrieving cholinergic balance through enzymatic acetylcholine (ACh) hydrolysis. In addition to hydrolysis of ACh at the brain cholinergic synapses and neuromuscular junctions, AChE also affects cell proliferation, differentiation, and responses to various insults. Through alternative splicing of its 3' end, AChE is considered to be one of the general stress-responding proteins, both in the brain and in the periphery. AChE

is glycosylphosphatidylinositol (GPI)-anchored protein, and efficient glypiation is necessary for proper localization and secretion. For more than 10 years, it has been known that differences in glycosylation affect the stability of the enzyme, but the functional consequences of altered glycosylation are still not understood. Pharmacokinetic profiling of the AChE glycoforms demonstrated a correlation between circulatory longevity and the number of attached N-glycans. Glycosylation of AChE was shown to be altered in breast cancer, but this was not studied in detail. Abnormally glycosylated forms of the enzyme also accumulate in the cerebrospinal fluid in some neurological disorders, and changes in AChE glycosylation were reported to be a potential diagnostic marker for Alzheimer's disease.

Contraception, which is a form of hormonal stress for the body, also affects glycosylation. Oral estrogen treatment induces an increase in the degree of branching and a decrease in fucosylation and sialyl Lewis x expression on α_1 -acid glycoprotein compared to individuals receiving no estrogens or transdermal estrogen treatment. The effects of oral estrogens are identical in both males and females, and they can be reduced by the administration of progestagen. The effects of oral estrogens on glycosylation of α_1 -acid glycoprotein are the opposite of those induced by inflammation, indicating that estrogens can modulate the glycosylation-dependent inflammatory actions of α_1 -acid glycoprotein. Interestingly, estrogens that are applied transdermally do not exert this effect on hepatic glycosylation.

Lectins in Stress

Some glycans on glycoconjugates have only structural roles, but some also take part in specific recognition processes. One of the major mechanisms by which glycoconjugates perform their molecular functions is the interaction with their specific molecular receptors, lectins. Hundreds of endogenous lectins function as physiological receptors for oligosaccharides that interpret molecular information encoded in glycans. They take part in numerous physiological processes including folding, intracellular transport, fertilization, regulation of the inflammatory response, and brain plasticity.

The best-known example of lectin function is inflammation, in which the interaction between lectins called selectins and carbohydrate structures on glycoproteins represents the first decisive step leading to the adhesion of circulating lymphocytes to the endothelium at the site of inflammation. Carbohydrate-lectin interactions are very interesting because they can be inhibited with small oligosaccharides that

are generally nontoxic and, using modern carbohydrate cycling technologies, are relatively inexpensive to prepare for therapeutic purposes.

The first indications that lectins might change in stress came from a study of a phenomenon only remotely associated with stress. Bardosi and colleagues were analyzing the influence of prolonged anesthesia on mannose receptor and some other lectins on murine peripheral blood polymorphonuclear leukocytes. They demonstrated reduced expression of mannose receptor and changes in the expression of receptors for several other sugars, indicating that prolonged anesthesia affects the regulation of lectin expression.

Evidence that psychological stress can influence lectins came from studies of Lauc and colleagues on lectins in livers of rats exposed to immobilization stress. Immobilization stress was found to influence galectin-3, a galactose-specific lectin, so that it binds to another nuclear lectin CBP67 (67-kDa carbohydrate binding protein). The formation of the complex from CBP67 and galectin-3 resulted in the binding of the galactose-specific galectin-3 to the glucose-affinity column, for which it shows no affinity under normal conditions. This is a very interesting effect because galectin-3 is involved in mRNA splicing and changes in its functions might have profound effects on the whole cell. However, whether this binding was mediated by protein-protein interactions or through lectinlike binding of galectin-3 to galactose residues on carbohydrate structures attached to CBP67 (as well as other details of this interaction) is not known.

Galectin-3 is a versatile galactoside-binding lectin that has been implicated in numerous cellular functions. It also appears to be affected by stress and, interestingly, different types of stress have exactly opposite effects on its expression. As shown by Dumić and colleagues in 2000, whereas exposure to UV light or transfer to *in vitro* conditions induces galectin-3 in cultured cells, immobilization stress *in vivo* results in a decrease in galectin-3 in mouse spleen and liver. The regulation of galectin-3 expression involves transcription factor nuclear factor (NF)- κ B, which connects galectin-3 with corticosteroids (and CRH) and places its expression downstream from hormonal signals in the stress-response pathway.

A major problem in studying changes of lectin activity in different physiological processes is the lack of adequate methods for measuring lectin activity in complex biological samples. A new method (Figure 3) using photoaffinity glycoprobes labeled with digoxin was recently developed, and it is hoped that it will enable easier identification of changes in lectins in different diseases. Until now, only one new lectin was found to appear in stress. It was found

Figure 3 Photoaffinity method for the detection of lectins. Photoaffinity glycoprobes containing target carbohydrate structures are incubated with biological samples to allow the formation of noncovalent complexes between the probe and lectin receptors in the sample. Illumination activates the photoreactive cross-linker, and it forms covalent bonds with neighboring molecules, mostly lectin receptors. The result is a lectin with a covalently incorporated digoxin tag (DIG) that can be easily identified with labeled antibodies against digoxin.

to bind to glucose-containing glycoprobes, and according to the electrophoretic mobility of the protein isolated from rat liver named CBP33.

Stress Affects the Activity of Glycosyltransferases

The carbohydrate parts of glycoconjugates are synthesized by sequential action of numerous GTs, enzymes that are specific for both the structure of the glycoconjugate acceptor and the monosaccharide that is being added. The appearance of novel or altered glycoconjugate structures in stress indicates that stress should somehow affect the activity of GTs, but the only GTs whose relation with stress have been studied up to now are the sialyltransferases (enzymes that transfer sialic acids to glycoproteins).

For some time it has been known that corticosteroids can change the activity of sialyltransferases *in vitro*. Breen and colleagues have shown that corticosteroids and other hormones from the adrenal gland significantly influence the activity of sialyltransferases *in vivo*. Adrenalectomy and the subsequent administration of corticosterone and/or aldosterone significantly influence the activity of sialyltransferases in various rat tissues. Whereas sialyltransferases in some tissues such as the kidney are apparently not influenced by adrenalectomy or by the addition of steroid hormones, sialyltransferases in the liver are under the negative control of corticosteroids. Adrenalectomy results in the increased activity of sialyltransferases in the liver that cannot be reverted to normal values by the administration of dexamethasone.

Enzymes that perform the same function in the brain react to same hormonal signals in the exactly opposite way. Adrenalectomy and the consequential lack of circulating corticosteroids lead to the decrease of total sialyltransferase activity in the brain. The subsequent administration of exogenous corticosteroids exhibits regional specificity, with the enzyme activities in the cortex, cerebellum, and brain stem being stimulated by both dexamethasone and aldosterone and enzyme activity in the hippocampus being stimulated only by aldosterone. Total sialyltransferase activity in some tissue does not represent the activity of a single enzyme but the sum of the activities of all enzymes that transfer sialic acids. Breen and colleagues also studied the effects of corticosteroids on two individual enzymes, $\alpha(2,3)$ -sialyltransferase and $\alpha(2,6)$ -sialyltransferase. Both enzymes transfer sialic acids, but they link them to different carbon atoms on the preceding sugar in the carbohydrate structure.

As shown by Dabelic and colleagues in 2004, immobilization stress affects sialyltransferase activity in different rat tissues. Acute and chronic stress have different effects, but, even more interesting, the same type of stress has opposite effects on sialyltransferase activity in different tissues. In general, stress induces sialyltransferase activity in extraneural tissues and suppresses the activity of the same enzymes in most brain tissues. The fact that same enzymes respond differently to the same hormonal signals depending on their cellular environment exemplifies the fact that the molecular setup of the targeted cell, and not hormonal signal by itself, is the decisive player in

Figure 4 Hypothetical model of the glycobiology of stress. Hormones mediate numerous stress-associated changes, and among them alter the activity of different glycosyltransferases. Changed activity of glycosyltransferases results in the appearance of different carbohydrate structures on glycoproteins, which could either present a novel structures with potential to interact with specific endogenous lectins or modify the activity of various membrane receptors. Although this has yet to be proven, it could be one of the mechanisms explaining why prolonged stress has different effects than acute stress. In the same time, it is known that stress is associated with changes in composition and activity of endogenous lectins, but the exact mechanisms linking stress and changes in lectin activity are still not known.

determining the direction and consequences of the stress response.

Model of Glycobiology of Stress

At the moment only several fragments of the glyco-biological mechanisms involved in the physiological response to psychological stress are known, but the complete picture is slowly emerging (Figure 4). Stress causes numerous changes in the circulating hormones, and many molecular details of this process are known. It is also known that corticosteroids affect the activity of at least one GT both *in vitro* and *in vivo*. The altered activity of GTs results in different carbohydrate structures attached to glycoproteins, and these changes have been demonstrated both in humans and in experimental animals. A change in the carbohydrate structures attached to a glycoprotein is a well-established way to change its structural and functional properties, and recently this was shown

to be one of the mechanisms that control the activity of membrane receptors. Although this type of glycosylation-mediated receptor modulation in stress still has to be proven, it is a very interesting hypothesis. On the other hand, new glycoconjugate structures could also represent novel signals on the cell surface that could alter the interaction of the cell with neighboring cells in a process analogous to the selectin-mediated adhesion of lymphocytes. Stress is also known to be associated with the appearance of novel lectins, but the exact mechanism of this process is not known. These lectins could be receptors for either novel or normal glycoconjugate structures, translating their structures into molecular functions. Although most of this is still speculative, it is hoped that more will soon be known about the molecular role of glycoconjugates, their lectin receptors, and GTs in the physiological response to psychological stress.

Control of Normal Gonadotropin Secretion

The Gonadotropin Response to Stressors: Cross-Talk between the Hypothalamic-Pituitary-Adrenal and the Hypothalamic-Pituitary-Gonadal Axes

Central Pathways Mediating the Stress Response

Stressors and the Reproductive Cycle

Glossary

<i>Amenorrhea</i>	The absence of menstruation, denoting a silent hypothalamic-pituitary-ovarian endocrine axis.
<i>Arginine vasopressin (AVP)</i>	An adjunct neurohormone in control of the hypothalamic-pituitary-adrenal endocrine axis. It is colocated with and released together with CRH in response to stressors.
<i>Corticotropin releasing hormone (CRH)</i>	The main neurohormone in control of the hypothalamic-pituitary-adrenal endocrine axis. Its release from the hypothalamic paraventricular nucleus is activated by stressors. It stimulates the pituitary to secrete adrenocorticotrophic hormone.
<i>Estradiol</i>	The main sex steroid secreted by the ovarian follicle.
<i>Follicular phase</i>	The first stage of the menstrual cycle, during which the process of folliculogenesis is completed through the maturation of the soon-to-be-ovulated dominant follicle.
<i>Follicle stimulating hormone (FSH)</i>	A gonadotropin that promotes the recruitment of a new cohort of follicles at the start of each follicular phase.
<i>Gonadotropin releasing hormone (GnRH)</i>	The hypothalamic structure responsible for the pulsatile release of GnRH, in a process that is essential for the normal function of the reproductive process.
<i>pulse generator</i>	Two hormones, follicle stimulating hormone and luteinizing hormone, released by the anterior pituitary following stimulation by GnRH.
<i>Gonadotropin</i>	
<i>Luteal phase</i>	The second stage of the menstrual cycle, when the ovulated follicle is transformed into a new structure, the corpus luteum, which secretes both estradiol and progesterone.

Luteinizing hormone (LH)

A gonadotropin that stimulates the release of estradiol from the maturing follicle and of progesterone from the corpus luteum.

Progesterone

The main sex steroid secreted by the corpus luteum. It prepares the uterus for the implantation of the fertilized egg.

Proopiomelanocortin (POMC)

The common precursor molecule to β -endorphin (an endogenous opioid peptide) and to α -melanocyte stimulating hormone. Both peptides modulate the gonadotropin response to stressors.

Control of Normal Gonadotropin Secretion

Hypothalamic Control: The Gonadotropin Releasing Hormone Pulse Generator

The hypothalamic-pituitary-gonadal (HPG) axis, which governs the reproductive system, is driven by the brain. Gonadotropin (FSH and LH) secretion by the anterior pituitary gland is controlled by the hypothalamus through the release of GnRH. GnRH, a 10-amino-acid peptide, is synthesized within several hypothalamic nuclei and released into the hypophyseal portal circulation to stimulate the release of both gonadotropins. This direct vascular connection between the hypothalamus and the anterior pituitary allows for the rapid and undiluted transport of minute amounts of GnRH to its target, the pituitary gonadotroph. Gonadotropins, in turn, act on the gonads, the ovaries or testes, to induce specific morphological changes and to stimulate the release of gonadal steroids, such as testosterone, estradiol, and progesterone. Constant communication between the several levels of the HPG axis through the negative feedback loop is essential for normal function; estradiol or testosterone secreted by the ovaries or testes continuously feeds back to the hypothalamus and pituitary to adjust GnRH, LH, and FSH secretion. The interruption of this negative feedback loop, for instance, following castration, results in an increase of GnRH, FSH, and LH release.

Significantly, GnRH is released from the hypothalamus in a pulsatile fashion (the GnRH pulse generator), and thus tonic secretion of gonadotropins is pulsatile in nature. Each pulse of LH consists of an abrupt and brief release of the hormone followed by an exponential decrease according to its half-life. A pulsatile GnRH stimulus is required to increase the transcription of the gonadotropin subunit genes.

Pathological events that interfere with the function of the GnRH pulse generator disrupt the pituitary-gonadal axis. For example, the complete absence of GnRH pulsatility results in a dormant reproductive axis, whereas lesser abnormalities, such as a decrease in GnRH pulse frequency, may interfere with proper reproductive function.

Gonadotropins and the Reproductive Cycle

The reproductive cycle, estrous cycle (in rodent and sheep) or menstrual cycle (in nonhuman primate and human) involves a remarkable coordination of hormonal secretion and morphological changes within the HPG axis. In the primate, a rise in FSH at the start of the follicular phase promotes the recruitment of a cohort of antral follicles from which the dominant follicle destined for ovulation will be selected. Stimulated by the pulsatile release of the gonadotropins, the dominant follicle grows exponentially and releases estradiol in amounts proportional to its size. The maturity of the dominant follicle is marked by a high estradiol release, which when a threshold is reached activates the positive estradiol feedback loop; this induces the ovulatory LH surge and ovulation. After ovulation, the dominant follicle is transformed into the corpus luteum, which secretes both estradiol and progesterone when stimulated by LH. Substantial progesterone secretion promotes uterine differentiation in preparation for implantation of the fertilized egg.

A proper pattern of GnRH and gonadotropin pulsatile release is required for the normal reproductive cycle to occur. In the human, for example, an optimal GnRH-LH pulse frequency of approximately one pulse every 90 min is required for normal folliculogenesis to occur during the follicular phase. A pulse frequency that is too low may fail to bring the recruited follicle to a timely maturation, and a too rapid pulse frequency may result in pathology (such as polycystic ovary syndrome).

The Gonadotropin Response to Stressors: Cross-Talk between the Hypothalamic-Pituitary-Adrenal and the Hypothalamic-Pituitary-Gonadal Axes

Effects of Stressors on Tonic Gonadotropin Release

The activation of the hypothalamic-pituitary-adrenal (HPA) axis by several types of stressors, such as immune/inflammatory challenges as simulated by the administration of endotoxin or cytokines, temporary restraint, or insulin-induced hypoglycemia, results in an inhibition of tonic pulsatile LH release, mainly

in the form of a decrease in LH pulse frequency. In women, psychogenic stress has also been related to lower basal tonic levels of FSH, LH, and estradiol compared to normal cycling women; these patients have reduced integrated 24-h LH and FSH concentrations, reduced LH pulse frequency, and increased LH interpulse interval.

Overall evidence suggests that this decrease in tonic pulsatile LH release is primarily related to a central action of stressors exerted through an inhibitory action on the hypothalamic GnRH pulse generator; a decline in the generator's ability to properly stimulate the gonadotroph, mainly through a reduction in the frequency of pulsatile GnRH release, appears to be the main mechanism involved. In addition, there is experimental evidence that stressors may also subtly influence the gonadotroph's responsiveness to GnRH and thereby decrease the amplitude of the gonadotropin response. This effect may reflect a pituitary action of adrenal corticosteroids released in response to the activation of the HPA axis by the stressor.

Effects of Stressors on the Surge Mode of Luteinizing Hormone Release

Data in the rodent and ewe also suggest that an immune/inflammatory challenge or restraint (and possibly other stressors) can also suppress the estradiol-induced ovulatory LH surge. In the rodent, this effect appears to be exerted at the level of GnRH perikarya, where the percentage of GnRH neurons expressing the c-fos protein and the GnRH primary transcript are significantly reduced by these stressors. The administration of a GnRH agonist concomitantly with the stressor completely restores the LH surge. In the ewe, endotoxin was shown to prevent the GnRH surge into the hypophyseal portal circulation, also suggesting a central effect of the challenge. Significantly, this inhibitory action is seen only if the stressor acts quite ahead of the expected time of the LH surge, primarily at the initial time of activation of the estradiol positive feedback signal.

Stressors and an Early Short-Term Rise in Gonadotropins

In addition to the previously mentioned inhibitory action of stressors on gonadotropin release, investigators have also reported a very transient rise in LH in rodents within the first hour of the response to various stressors, such as handling; restraint; exposure to ether or to a novel environment; or visual, audio-genic, and thermal stressors. This rapid and transient stimulatory effect of stressors on tonic LH release has been reported mostly in the intact, but generally not in the castrated, male rat, and in men but not women.

The mechanisms behind this phenomenon and its role in the stress response remain to be elucidated.

Central Pathways Mediating the Stress Response

The Hypothalamic Paraventricular Nucleus

The paraventricular nucleus (PVN) plays a pivotal role in the response to stressors. The neuroendocrine activation of the HPA axis by stressors involves the release of two neuropeptides, corticotropin releasing hormone (CRH) and AVP, from discrete populations of hypophysiotrophic neurons in parvocellular areas of PVN. These two neuropeptides, which are colocalized within perikarya of PVN neurons and in secretory granules, play a complementary role in mediating the effects of stressors on the HPA axis (see [Figure 1](#)).

There is good experimental evidence for an active mediatory role by CRH in the inhibition of GnRH and gonadotropins that follow stressors. In the non-human primate, the administration of a CRH receptor antagonist or of a drug decreasing endogenous CRH activity prevents not only the cortisol increase but also the inhibition of pulsatile GnRH–LH release induced by stressors such as an immune/inflammatory challenge ([Figure 2a](#)) or insulin-induced hypoglycemia. Similar mediatory effects of a CRH antagonist or of CRH antiserum have been reported in the rodent after various stressors, except in the response to an inflammatory challenge. The latter is in a marked difference with the primate. The administration of

CRH also results in a rapid inhibition of pulsatile LH release and in a decrease in the frequency and duration of GnRH pulses. Data in the nonhuman primate suggest that this inhibitory action is not mediated by downstream activation of the pituitary–adrenal axis: indeed, the inhibitory effects of a CRH infusion on pulsatile LH release cannot be mimicked by adrenocorticotrophic hormone (ACTH) infusion, are not reversed by treatment with metyrapone (an inhibitor of adrenal steroidogenesis), and persist following adrenalectomy.

Data in CRH-deficient male and female mice indicate that stressors such as restraint or food withdrawal can still inhibit tonic LH secretion or the proestrus LH surge, suggesting that molecules other than CRH may also play a role. Although there fewer data, AVP has also been shown to mediate the inhibitory action of certain stressors on the HPG axis and conceivably may take over in the CRH-deficient animal. In the ovx monkey, the inhibitory effects of a central infusion of interleukin (IL)-1 on pulsatile LH release are prevented by the co-administration of an AVP antagonist, even though the antagonist is without effect on the cortisol increase ([Figure 2b](#)). Some, but not all, investigators also report that the same antagonist prevents hypoglycemia-induced LH suppression in ovx and in male monkeys.

The Endogenous Opioid Peptides

There is substantial evidence to indicate that the inhibitory action of CRH and of most stressors on pulsatile GnRH–LH release occurs at suprapituitary sites that not only involve the neuroendocrine HPA axis but also mediation by endogenous opioid peptidergic pathways. Endogenous β -endorphin is known to be a powerful inhibitor of the GnRH pulse generator; for instance, during the luteal phase of the menstrual cycle of the human and nonhuman primate, there is a marked decreased in LH pulse frequency that parallels elevated endogenous β -endorphin activity and that is prevented by the administration of naloxone, a μ -opioid receptor antagonist. Hypothalamic β -endorphin activity is stimulated by CRH and by stressors. Naloxone administration also prevents the CRH- or AVP-mediated suppression of GnRH–gonadotropin release and restores pulsatile LH secretion ([Figure 3a](#)). This opioid antagonist also prevents the LH inhibition that follows several types of stressors, except for insulin-induced LH inhibition.

β -Endorphin derives from POMC, a large glycoprotein precursor molecule synthesized primarily in the hypothalamus and pituitary gland. Posttranslational processing of POMC is tissue-specific and in the hypothalamus yields not only β -endorphin but also α -melanocyte stimulating hormone (α -MSH).

Figure 1 Main pathways mediating the inhibitory effects of stressors on pulsatile gonadotropin release. α -MSH, α -melanocyte stimulating hormone; β -E, β -endorphin; ACTH, adrenocorticotrophic hormone; AVP, arginine vasopressin; CRH, corticotropin releasing hormone; FSH, follicle stimulating hormone; GnRH, gonadotropin releasing hormone; LH, luteinizing hormone; POMC, proopiomelanocortin; PVN, paraventricular nucleus.

(1992) Vasopressin mediates the interleukin-1 α -induced decrease in LH secretion in the ovariectomized rhesus monkey, *Endocrinology* **131**, 153–158, Copyright 1992, The Endocrine Society.

α -MSH has been shown to antagonize some of the actions of β -endorphin and may function as an endogenous opioid antagonist. In fact, α -MSH antagonizes the inhibitory action of exogenously administered β -endorphin on LH release and restores normal pulsatile LH release in ovx monkeys treated with CRH (Figure 3b) or subjected to an immune/inflammatory challenge. These data support the notion that post-translational processing of POMC may represent an important step in the response mechanisms to stressors and that the ratio of β -endorphin to α -MSH may be more significant than the absolute β -endorphin concentration in determining the ultimate effects of stressors on pulsatile LH release.

Stressors and the Reproductive Cycle

Stress and Amenorrhea

The reproductive cycle requires a remarkable coordination of hormonal secretion and morphological changes within all levels of the hypothalamic-pituitary-ovarian-uterine axis. Thus, it is not surprising

that stressors can disrupt the normal estrous or menstrual cycle. If sufficiently intense or chronic, stressors can completely interrupt the cycle. In women, psychogenic stress, usually the result of overt or latent psychological disturbances, is known to interfere with normal reproductive function and thought to be a common cause of amenorrhea in a syndrome known as functional hypothalamic chronic anovulation (FHCA). When fully established, the syndrome is characterized by ovarian quiescence, amenorrhea, and infertility. Several studies in the human underscore the association among FHCA, increased HPA activity in the form of an amplified circadian cortisol excursion, and low basal tonic levels of FSH and LH coupled with reduced LH pulse frequency.

Stress and Menstrual Cycle Defects

Although the long-term consequences of chronic stress may include amenorrhea and infertility and result in the full-blown FHCA syndrome, more recent data also demonstrate that stressors that initially are

Figure 3 Reversal of the inhibitory effects of CRH on pulsatile LH release. a, By naloxone (Nx); b, By α -MSH. Reprinted with permission from (a) Gindoff, P. R., Ferin, M. (1987) Endogenous opioid peptides modulate the effect of corticotropin-releasing hormone (CRH) on gonadotropin release in the primate, *Endocrinology* **121**, 837–842, Copyright 1987, The Endocrine Society; and (b) Shalts, E., Feng, Y. J., Ferin, M., Wardlaw, S. L. (1992) α -Melanocyte-stimulating hormone antagonizes the neuroendocrine effects of corticotropin-releasing factor and interleukin-1a in the primate, *Endocrinology* **131**, 132–138, Copyright 1992, The Endocrine Society.

of an insufficient intensity to induce amenorrhea may nevertheless produce temporary cyclic defects.

Prolongation of the follicular phase As shown in the ewe and monkey, endotoxin administration, mimicking an inflammatory/immune challenge, or exercise during the follicular phase results in a lengthening of the follicular phase and in the interruption of the normal follicular estradiol profile. The stressor prevents the development of high-frequency LH pulses that are the essential stimulus for the preovulatory increase in estradiol secretion; without these, the estradiol rise is curtailed and the preovulatory LH surge is delayed. Significantly, in the monkey, the delay in the resumption of a normal follicular phase greatly exceeds the duration of the stress challenge itself.

Inadequate luteal phase In the monkey, a short-term inflammatory/immune challenge or a psychogenic-like stress, whether confined to the follicular or luteal phase of the menstrual cycle, invariably result in reduced luteal function, as demonstrated by overall diminished progesterone and inhibin A secretion during the luteal phase (Figure 4). In many animals, these short-term stress challenges continue to interfere with normal luteal function through the first or two subsequent stressor-free cycles. The lower progesterone levels are related to the decrease in LH induced by the stressor. Inadequate luteal phases have also been reported during exercise, suggesting that this syndrome may well represent a general initial response to stressors and/or energy-related demands in the normal cyclic female.

Figure 4 Inadequate luteal phase following a 10-day psychogenic-like stress. a, During the follicular phase; b, During the luteal phase. Illustrated are daily levels of estradiol during the follicular phase (triangles) and of progesterone during the luteal phase (shaded areas) throughout two control menstrual cycles, the stress cycle, and two poststress cycles. Luteal progesterone secretion is significantly decreased in the stress cycle and in the first of the two poststress cycles (numbers within the shaded areas are integrated luteal progesterone values). Reprinted with permission from Xiao, E., Xia-Zhang, L., Ferin, M. (2002) Inadequate luteal function is the initial clinical cyclic defect in a 12-day stress model that includes a psychogenic component in the Rhesus monkey, *Journal of Clinical Endocrinology & Metabolism* 87, 2232–2237, Copyright 2002, The Endocrine Society.

Premature ovulatory luteinizing hormone surge
Studies in the primate have shown that the activation of the HPA axis by endotoxin or IL-1 in the mid- to late follicular phase (but not at other stages of the cycle) results in a large release of LH. Data in the monkey suggest that progesterone, which is released in small amounts by the adrenals in response to the stressor, may be responsible for this acute release of LH because this effect is prevented by a progesterone or CRH antagonist. Smaller increases in LH have also been reported in women following exercise during the mid-follicular phase.

The precise physiopathological significance of these three cyclic defects in response to a stressor during the menstrual cycle remains to be further studied in patients. The data, however, suggest that the HPG axis is closely monitored by the brain and that a stress challenge, even one not sufficient or extended enough to interrupt the cycle and to result in amenorrhea, may well induce endocrine changes too subtle to be appreciated in the clinical environment but nonetheless substantial enough to temporarily impact on fertility or to provide a temporary suspension of pregnancy in suboptimal conditions. For instance, decreased luteal progesterone secretion in response to a stressor may interfere with the process of implantation of a fertilized egg and result in spontaneous abortion by delaying the endometrial changes required for proper implantation. Prematurely elevated LH concentrations in the follicular phase may damage the maturing follicle and/or oocyte and desynchronize the ovulatory signal from a timely follicular maturation process and thereby result in early pregnancy loss.

<i>Autoimmunity</i>	Immune response directed at self antigens (belonging to the body of the individual), giving rise to antibodies against these antigens.
<i>Euthyroid</i>	Normal thyroid function.
<i>Graves' disease</i>	A multisystem autoimmune disease characterized by hyperthyroidism, enlarged thyroid gland (goiter), and frequently eye changes.
<i>Thyroid peroxidase (TPO)</i>	An enzyme in the thyroid gland involved in thyroid hormone synthesis.
<i>Thyrotoxicosis</i>	A disease caused by an excess of thyroid hormones; also called hyperthyroidism.
<i>Thyrotropin (TSH)</i>	The thyroid-stimulating hormone, which after release from the pituitary stimulates the thyroid gland to synthesize and release thyroid hormone.

Introduction

Thyrotoxicosis is a syndrome characterized by the clinical and biochemical manifestations of thyroid hormone excess in the target tissues of thyroid hormone. The most prominent clinical features of thyrotoxicosis are weight loss despite increased appetite, palpitations and tachycardia, fine tremor of the fingers, heat intolerance, perspiration, and a warm moist skin, all readily explained from an increased metabolic rate induced by thyroid hormone excess. Many patients also suffer from nervousness, irritation, anxiety, or mood disturbances, especially depression. Thyrotoxicosis is a very prevalent disease, occurring more frequently in women than in men. The annual incidence rate is approximately 0.4 per 1000 women and 0.1 per 1000 men.

Thyrotoxicosis can be caused by various diseases such as Graves' disease, toxic multinodular goiter, toxic adenoma, and destructive thyroiditis. Most prevalent, however, is Graves' disease, which is present in 75–90% of all thyrotoxic patients. Its relative frequency is dependent on ambient iodine intake, being lower in iodine-deficient areas. The peak incidence of Graves' disease is between ages 20 and 50 years. Graves' disease is an autoimmune disease characterized by antibodies directed against the thyrotropin receptor (TSH-R) on the surface of follicular epithelial cells in the thyroid gland; these antibodies

(called thyroid-stimulating immunoglobulins) after binding to the TSH-R stimulate the thyroid gland to synthesize and release thyroid hormone, thereby causing the clinical picture of thyrotoxicosis. The disease is referred to as Graves' hyperthyroidism (GH), a typical autoimmune thyroid disease. At the other end of the spectrum of autoimmune thyroid diseases is chronic lymphocytic thyroiditis, also called Hashimoto's disease, characterized by the presence of autoantibodies against thyroid peroxidase (TPO), an enzyme involved in thyroid hormone synthesis. Hashimoto's disease frequently results in hypothyroidism. TPO antibodies are also found in the majority of patients with Graves' hyperthyroidism.

Autoimmune thyroid disease frequently runs in families. The autoimmune reaction against thyroid antigens is thought to develop against a certain genetic background, provoked by environmental factors. Recent twin studies have indicated that genes are responsible for approximately 80% of the risk to get Graves' disease. Among these genes are HLA-DR3, CTLA-4, and PTPN-22, but their contribution is relatively small and most of the genes involved are still unidentified. It follows that 20% of the risk on Graves' disease is derived from the environment. Smoking is a clear risk factor for Graves' hyperthyroidism (especially for the eye changes in Graves' disease) but not for Hashimoto's hypothyroidism; smoking might even protect against the occurrence of TPO antibodies. Ever since the early descriptions of Graves' disease, stress has been implicated in its pathogenesis.

Historical Observations

In August 1803, Elizabeth S., a 21-year-old patient of Dr. Parry, became acutely frightened when she lost control of her wheelchair and careered downhill. Two weeks later she developed swelling of the thyroid gland, palpitations of the heart, nervous troubles, marked pulsation of the carotid arteries, and a small hard regular pulse of 96. Since Dr. Parry's description, the relation between stressful life events and the precipitation of clinical Graves' disease has been underlined by many other physicians, including Graves and von Basedow. In humans, a sudden fright may cause acute exophthalmos and thyroid enlargement with pulsating thrills (*Schreckbasedow*). The French refer to the thyroid as *la glande d'emotion*. An increase in the incidence of Graves' disease has been observed during every major war since the Franco-Prussian conflict, and the German term *Kriegsbasedow* reflects this association. Indeed, hospital admissions for Graves' disease increased fivefold in occupied Scandinavian countries during

World War II, returning to normal levels after liberation. Many textbooks in the second half of the twentieth century thus conclude that a period of severe emotional stress almost always precedes the onset of Graves' disease. The occurrence of Graves' hyperthyroidism in President George Bush, Sr., shortly after the Gulf War in 1991 apparently underlines this conclusion. The conclusion, however, is not supported by all studies. Environmental stress caused by the civil unrest in Northern Ireland was not associated with a higher incidence of thyrotoxicosis. Moreover, defining and quantifying stress is difficult. The death of a spouse is generally viewed as a stressful life event, highly distressing for the survivor after a long-standing marriage of mutual love and caring. But the death of an abusive wife-beating husband might come as a welcome relief to his widow. In addition, we may ask: which came first, the stress or Graves' disease? Increased anxiety and hyperreactivity to stressors might be an early manifestation of Graves' hyperthyroidism, preceding other symptoms and signs of the disease by months.

Association between Stress and Graves' Disease

Since the early 1990s there have been six case-control studies on the relation between stress and the onset of Graves' hyperthyroidism (see [Table 1](#)). The cases are well-documented patients with Graves' hyperthyroidism and were compared with controls who in general are reasonably well selected at random from a healthy population and matched for sex and age, although not always for marital and social status. Stress evaluation is standardized, applying either interviews or questionnaires, asking for stressful life events in the year prior to the diagnosis or prior to the first symptoms and signs of Graves' hyperthyroidism. The results have always been obtained in a retrospective manner, making all studies liable to recall bias. It has been argued that memory is differentially affected by mood, and, in particular, that negative events or memories are better recalled in the presence of a negative affect. Because hyperthyroid patients frequently have depressive symptoms, their negative affect could explain the increased reporting of negative life events in comparison with healthy controls. To avoid the effect of hyperthyroidism, some studies have chosen to perform the stress evaluation after the patient's thyroid function has been restored to normal levels; in doing so, the time interval for memorizing past events becomes longer, which by itself may increase recall bias. Evaluating stressful life events in the year prior to the first occurrence of hyperthyroid symptoms and signs is preferable to evaluating them

Table 1 Case-control studies on the relationship between stress and the onset of Graves' hyperthyroidism

Author (year)	Cases ^a		Controls ^b		Stress evaluation			Relation stress and Graves
	n	%	Matching criteria	Origin	Method ^c	Period	When done	
Winsa et al. (1991)	208	82	A, S	General population	1	1 year prior to diagnosis	Hyperthyroid; <2 wk after diagnosis	Yes
Sonino et al. (1993)	70	83	A, S, M, C	Advertisement, hospital staff	2	1 year prior to first signs	Euthyroid; 10 months (3–39) after first sign	Yes
Kung (1995)	95	84	A, S, M, C	Volunteers in community	1	1 year prior to diagnosis	Hyperthyroid; at referral	Yes
Radosavljevic et al. (1996)	100	93	A, S	Outpatients with other conditions	2	1 year prior to diagnosis	Not stated	Yes
Yoshiuchi et al. (1998)	228	80	A, S	Healthy controls from database	1	1 year prior to diagnosis	<1 month after diagnosis	Yes
Matos-Santos et al. (2001)	31	71	A, S, M, C	Preventive medicine appointments	1	1 year prior to first symptoms	Euthyroid after treatment	Yes

^aAll Graves'.^bA, age; C, social class; M, marital status; S, sex. Number of controls same as number of cases, except for Winsa (1991) study with 372.^c1 = Sarason's questionnaire Life-Event Survey, with modifications in Yoshiuchi study 5; 2 = Paykel's interview for Recent Life Events.

in the year prior to the time at which the diagnosis was made by the physician, but it cannot always be known with certainty when precisely the first symptoms and signs started. Nevertheless, all six studies observed more stressful life events in the patients with Graves' hyperthyroidism than in the controls.

Winsa et al. reported more negative stressful life events in patients than in controls (odds ratio, OR, 1.33; 95% confidence interval, CI, 1.20–1.48); the odds increased with increased scores attached to the negative life events, from OR 1.0 for a score of 0 points to OR 6.3 (95% CI 2.7–14.7) for a score of ≥ 5 points; the number of positive events was similar in both groups. The prevalence of divorce was higher and job satisfaction was lower in patients than in controls, but a score for mastery in life (apart from work) did not differ between the groups. Patients had type A behavior not more frequently than controls (28 vs. 18%, not significant). The effect of negative life events was similar in patients with or without familial occurrence of thyroid disease, implying different mechanisms for these two risk factors.

Sonino et al. also reported more life events in patients than in controls (1.51 vs. 0.54, $p < 0.001$); patients had more independent events (defined as not likely to be a consequence of the illness) and events with negative impact than controls, according to a blind rater.

Kung likewise observed a higher number of negative events in patients than in controls (0.94–1.54 vs. 0.38–0.88, $p = 0.003$) and higher negative event

scores (1.55–2.69 vs. 0.58–1.45, $p = 0.002$); the reporting of positive and neutral events was similar in both groups. Groups did not differ in coping ability, but Graves' patients experienced more daily hassles (12.11–17.05 vs. 6.36–11.00, $p = 0.001$) and higher hassle scores (17.55–25.34 vs. 8.92–15.87, $p = 0.001$).

Radosavljevic et al. reported a mean number of 3.18 stressful life events in patients versus 1.85 in controls ($p = 0.0001$). Life events that were significantly more prevalent in patients than in controls were change in time spent on work, unemployment, arguments at work, change in work conditions, increased arguments with spouse or fiancé, hospitalization of family member for serious illness, and moderate financial difficulties.

Yoshiuchi et al. found a lower score for problem-oriented coping skills and a higher prevalence of smoking but not of daily hassles in patients than in controls. After adjustment for these variables, stressful life event were significantly associated with the risk of Graves' disease in women but not in men; the relative risk was 7.7 (95% CI 2.2–27) for women with highest stress scores compared with lowest stress scores.

Matos-Santos et al. reported a significantly greater number and impact of negative stressful life events in patients with Graves' disease than in healthy controls.

Taken together, these six studies, despite their limitations, provide fair evidence for the association

between negative stressful life events and the onset of Graves' hyperthyroidism. The lack of evidence for such an association in a previous study by Gray and Hoffenberg might be explained by the inclusion of thyrotoxic patients without Graves' disease.

Stress and Graves' Disease: A Causal Relationship?

The case-control studies do not provide conclusive evidence that stress plays a causative role in the immunopathogenesis of Graves' hyperthyroidism because of their retrospective nature. It would be ideal to have prospective studies with regular stress evaluation in euthyroid subjects at risk for developing Graves' disease to see whether the stress load is higher in subjects who become hyperthyroid than in subjects who remain euthyroid; such studies have not been done. But there have been two prospective studies in patients with Graves' hyperthyroidism who were investigated when euthyroid on antithyroid drug treatment. In both studies, Yoshiuchi and Fukao observed higher scores of daily hassles in patients who experienced recurrent hyperthyroidism after the discontinuation of antithyroid drugs than in patients who remained euthyroid.

Matos-Santos et al. evaluated stressful life events in Graves' hyperthyroid patients and controls and also in 31 patients with toxic nodular goiter – a nonautoimmune disease causing thyrotoxicosis. The number and impact of negative stressful life events were higher in patients with Graves' disease than in patients with toxic nodular goiter or controls, whereas the difference between patients with toxic nodular goiter and controls was not significant. The data suggest that hyperthyroidism itself is not responsible for more stressful life events preceding the diagnosis of thyrotoxicosis; the data, rather, support the view that stress precipitates autoimmunity.

There are almost no data on a putative relationship between stress and TPO antibodies, an early marker of autoimmune thyroid disease, except a study by Strieder et al., who compared euthyroid women with or without TPO antibodies. No difference was found between both groups in the number of stressful life events, the number of daily hassles, or the scores of negative and positive affect scales. Stress apparently seems more related to thyroid autoimmunity against the TSH receptor, causing Graves' hyperthyroidism. This is underlined by a significant increase in the incidence of Graves' disease in eastern Serbia during the civil war in former Yugoslavia. The specificity of this finding is indicated by the fact that during the same time period the incidence of toxic nodular goiter did not increase. Chiovato et al. did

not find a single case of Graves' hyperthyroidism in patients with panic disorder; they hypothesize that failure to activate the hypothalamic-pituitary-thyroid axis by chronic endogenous stress due to panic disorder (as opposed to exogenous stress due to life events) might explain why panic disorder does not precipitate Graves' hyperthyroidism.

It can be concluded that the association between stressful life events and the onset of thyrotoxicosis is specific for Graves' hyperthyroidism and that stress probably is involved in the immunopathogenesis of Graves' disease. How stress contributes to the precipitation of the disease is presently poorly understood. The activation of the hypothalamus-pituitary-adrenal axis would be expected to cause immunosuppression rather than autoimmunity. Paradoxically, however, a surprising increase in Graves' disease was reported in patients with multiple sclerosis undergoing anti-T cell immunosuppressive therapy. Regulatory CD4⁺ CD25⁺ T-cells may be involved. These cells suppress autoimmune disease; if these cells are more sensitive to immunosuppression and slower to regenerate than other T cell subsets, this may explain the paradoxical observations.

Introduction

Diagnosis of Complicated Grief

Outcomes and Risk Factors of Complicated Grief

Treatment

Glossary

<i>Complicated grief</i>	The experience of debilitating grief symptoms 6 months postloss and beyond.
<i>Separation anxiety</i>	Fear and anxiety provoked by the threat of separation from a primary attachment figure.

Introduction

Grieving describes the emotional state associated with losing a person to whom one is attached. Bereavement is a natural part of life, and the normal process of grieving is self-limited and is most commonly not a cause for clinical concern. Despite this, research shows that bereavement is one of the most challenging life experiences and that bereaved people, as a group, have a higher risk of mortality and morbidity. This increased risk is largely a function of the significant minority for whom the process of grieving becomes overwhelming, causing distress and disruption for an unusually long period. In these cases of

complicated grief, there is cause for clinical concern and appropriate interventions are required.

Normal Grief

The vast majority of bereaved individuals experience normal or uncomplicated grief. Although normal grieving is painful and disruptive initially, eventually bereaved survivors are able to accept the loss as a reality and move on with life. They are able to carry out daily functions and gradually begin to enjoy leisure activities.

One of the most commonly cited models of normal grief resolution among professionals and laypersons is Kubler-Ross's stage theory. This theory proposes orderly progression through the following stages: disbelief or shock, yearning, anger and protest, depressed mood, and ultimate acceptance of the loss. Recent research attempting to test this theory suggests that multiple stages may be present simultaneously. Instead of clear-cut stages, on average the bereaved person's distress gradually declines as acceptance increases.

For the first few months following the loss, the symptoms of uncomplicated grief are difficult to distinguish from complicated grief. After 6 months, however, the majority of bereaved individuals have reached some level of acceptance, are able to engage in productive and enjoyable activities, and can remain connected with others while developing new relationships. Bereaved survivors who are experiencing adjustment difficulties 6 months postloss, such as suicidal thoughts and gestures, major depressive disorder (MDD), or posttraumatic stress disorder (PTSD), and those who are experiencing persistent symptoms of grief are a cause for clinical concern.

Resilient Responses to Bereavement

Some bereaved people exhibit little or no distress post-loss. Bereavement experts have debated the causes for this. Some have suggested that minor grief

symptoms may signify a more superficial attachment to the deceased. Others have suggested that low distress levels following a significant personal loss are the sign of a maladjusted, emotionally distant person. The traditional view has been to see the lack of grief as denial or an inhibition of the normal grieving process. Thus, these bereaved people have been counseled to assist in the resolution of their latent grief. Studies have shown, however, that some of these subjects may have a healthy resilience to loss that allows them to recover with little disruption in functionality. By this view, resilient subjects have little to benefit from grief counseling because they show little evidence of struggling internally with the loss. Still, using the absence of grief as a marker for resilience is somewhat controversial. Because grief intensity is in direct proportion to the attachment to the deceased, the absence of grief is truly a mark of experienced resilience only if the attachment to the deceased was very strong. This is often difficult to assess. However, there is much to be gained in further understanding the resilient response so that individuals struggling with grief can adopt some of these successful coping strategies.

Diagnosis of Complicated Grief

Descriptive Features

The term complicated grief has been used interchangeably with pathological grief, abnormal grief, atypical grief, and pathological mourning. At one time traumatic grief was also used, but since the attacks on September 11, 2001, this term has been reserved for the psychological reaction following a traumatic event and for grief following the loss of a person during such an event. The term complicated grief is now primarily used to describe the experience of losing a person to natural causes.

Complicated grief can be described as a state of chronic mourning. The bereaved survivor cannot accept the reality of the loss and as a result is reluctant to make any adaptations to life. The psychological distress is characterized by intense yearning for the absent loved one. His or her constant focus on the absence of the deceased creates a barrier to maintaining and forging relationships. This simply heightens the sense of isolation the bereaved person feels. This state of grieving has been shown to be a risk factor for suicidal thoughts and ideation, over and above any confounding influences of diagnoses such as MDD.

Diagnostic Criteria

The proposed set of diagnostic criteria for complicated grief from the *Diagnostic and Statistical Manual of Mental Disorders* (5th edn.; DSM-V) is shown in Table 1. This diagnosis requires that the bereaved person be persistently yearning for the deceased in a manner that disrupts his or her daily life. In addition, four of the following eight symptoms must be experienced to a distressing and disruptive degree (i.e., several times a day, interfering with social or occupational functioning): trouble accepting the death, inability to trust others since the loss, excessive bitterness related to the death, feeling uneasy about moving on, detachment from formerly close others, feeling life is meaningless without the deceased, feeling that the future holds no prospect for fulfillment without the deceased, and feeling agitated since the death. Also, as mentioned earlier, the severity and number of symptoms must persist for at least 6 months, regardless of when those 6 months occur in relation to the loss. This allows both chronic and delayed types of grief to be included in the diagnosis.

There is evidence to support the 6-month delay in making a complicated grief diagnosis. It is important

Table 1 Criteria for complicated grief proposed for DSM-V^a

Criterion A	Yearning, pining, and longing for the deceased; yearning must be experienced at least daily over the past month or to a distressing or disruptive degree
Criteria B	In the past month, the person must experience four of the following eight symptoms as marked, overwhelming, or extreme: - Trouble accepting the death - Inability to trust others since the death - Excessive bitterness or anger about the death - Feeling uneasy about moving on with his or her life (e.g., difficulty forming new relationships) - Feeling emotionally numb or detached from others since the death - Feeling life is empty or meaningless without the deceased - Feeling the future holds no meaning or prospect for fulfillment without the deceased - Feeling agitated, jumpy, or on edge since the death
Criterion C	The symptom disturbance causes marked dysfunction in social, occupational, or other important domains
Criterion D	The symptom disturbance lasts at least 6 months

^aFrom Prigerson, H. G., Vanderwerker, L. C. and Maciejewski, P. K. (in press). Chapter 8. In: Stroebe, M., Hansson, R., Schut, H. & Stroebe, W. (eds.) *Handbook of bereavement research and practice: 21st century perspectives*. New York: American Psychological Association Press.

to allow time for the normal grieving symptoms to subside, in order to detect those who are unusually distressed. This allows for a more conservative threshold for diagnosing complicated grief, and we are less likely to include false-positive patients whose symptoms will eventually naturally resolve. Also, patients still experiencing symptoms at 6 months were found to be less likely to experience natural grief resolution and more likely to experience negative outcomes 13–23 months postloss.

Differential Diagnosis

Bereavement may be complicated by a number of other psychiatric disorders. Major depression is the primary reported disorder following the death of a loved one. However, complicated grief symptoms form a symptom cluster distinct from the depressive or anxiety-related symptom clusters. Depressive symptoms include depressed mood, psychomotor retardation, and decreased self-esteem; complicated grief is specifically associated with yearning, disbelief, detachment, bitterness, and anger related to the death. PTSD is another complication associated with bereavement, especially if the death was associated with a traumatic incident. Studies have shown, however, that unlike PTSD, complicated grief in response to a natural death is not accompanied by fears of violent harm to self and others, hypervigilance, or avoidance of a fear-inducing stimulus. Complicated grief may, of course, occur in conjunction with PTSD in the context of the violent death of a loved one. In fact, complicated grief does frequently occur in addition to MDD and/or PTSD; however, many cases of complicated grief are currently missed due to the reliance on guidelines for psychiatric diagnoses provided in the DSM-IV.

Other factors that set complicated grief apart from MDD and PTSD are the risk factors, outcomes, and responses to treatment.

Outcomes and Risk Factors of Complicated Grief

Physical and Psychological Outcomes

Bereaved subjects suffering from complicated grief have been found to suffer myriad negative consequences. Long periods of distress and dysfunction may be responsible for this. Complicated grief has been associated with heightened risks of cancer, hypertension, cardiac events, and suicidal ideation. It has also been associated with disability, functional impairment (social, familial, and occupational dysfunctions), hospitalization, and reduced quality of life. Those suffering from complicated grief are also more likely to engage

in unhealthy behaviors such as alcohol and cigarette consumption. Psychologically, patients with complicated grief are more likely to develop comorbid conditions with depressive symptoms and major depressive episodes. The relative risks for negative health outcomes associated with complicated grief are summarized in Table 2.

Risk Factors

Given the negative outcomes of untreated complicated grief, the identification of at risk individuals should be a priority for clinicians. Several possible risk factors for the development of complicated grief have been identified in studies. One important risk factor is the closeness of the relationship between the bereaved and the deceased. Relationships that were dependent, confiding, and close led to the poorest bereavement adjustment. In fact, relationships that are conflicted at baseline result in lower rates of bereavement disorders. The belief that complicated grief is fundamentally an attachment disturbance is borne out by the identification of weak parental bonding in childhood as a risk factor for complicated grief. Bereaved people with a damaged sense of security due to childhood abuse or severe neglect have a higher risk of experiencing complicated grief as adults. Childhood separation anxiety was identified as a risk factor as well. Also, individuals who are generally averse to change of any kind (e.g. lifestyle changes) are more likely to experience complicated grief. Two factors that have been found to reduce the risk of complicated grief are advance preparation for the death and a strong support network.

Thus, in summary, patients who have attachment difficulties at baseline and who feel unprepared and unsupported during and after the death are at higher

Table 2 The relative risk of some negative health outcomes among bereaved individuals diagnosed with complicated grief at 6 months postloss^a

Health outcome (incidence)	Relative risk	Confidence interval (95%)
High systolic blood pressure at 13 months post loss	1.11	1.02–1.20
Depression at 13 months post loss	2.72	0.84–8.81
Changes in smoking at 13 months post loss	16.7	0.86–320.4
Changes in eating at 13 months post loss	7.02	1.62–30.6
Heart trouble at 25 months post loss	1.15	1.04–1.27
Problems with alcohol at 25 months post loss	1.25	0.98–1.63

^aFrom El-Jawahri, A. and Prigerson, H. G. (in review). Evidence-based guidelines for the diagnosis and treatment of complicated bereavement. *Journal of Palliative Medicine*.

risk of experiencing complicated grief. This indicates that interventions geared toward preparing caregivers for the impending death of a loved one, as well as promoting secure alternative engagements to others, would be helpful in the treatment of persistent grief symptoms.

Treatment

As previously mentioned, there is a strong connection between a lack of preparedness for the death of a loved one and the development of complicated grief postloss. Thus, it would seem that interventions administered preloss might prove promising at reducing bereaved survivors' risk of complicated grief. Clinicians who provide palliative care might extend their efforts to the caregivers of a dying patient, encouraging them to say goodbye and accept the impending loss. This would entail a greater comfort with prognosticating the end of life, an issue that is fraught with controversy and complexity.

Just as physician involvement and communication can increase the chances of caregivers being prepared for the death, similarly, hospice enrollment has been shown to reduce the risk of MDD. This is consistent because hospice enrollment usually requires acceptance that death will occur within 6 months, intimating caregiver preparedness. In the Netherlands, a study found that caregivers of cancer patients who died by euthanasia were less likely to experience disruptive grief symptoms than those whose loved ones died a natural death. This, too, is consistent, given that euthanasia implies a greater acceptance of the patient's prognosis on the part of the caregivers.

Concrete interventions to help caregivers prepare for the loss center around proactively assisting caregivers to "hope for the best, plan for the worst." Traditionally, getting one's affairs in order include making an effort to visit the patient and expressing appreciation, regrets, and reassurances before it is too late. In addition, health-care professionals should not hesitate to recommend hospice and palliative care services when their need becomes apparent. An earlier referral to a hospice has been shown to be beneficial in promoting a peaceful death and lessening distress for caregivers.

As noted earlier, after the loss, in most cases grief is manageable and resolves naturally, requiring no professional interventions. Bereavement interventions are more appropriate for those individuals who are particularly at risk or those who present with unremitting, severely disruptive grief symptoms six months postloss.

Research has shown that interventions such as nortriptyline and interpersonal psychotherapy, which

were effective for the treatment of depressive symptoms, were not effective in treating grief symptoms. To date, there have been no randomized controlled trials of pharmacotherapies for the reduction of grief-symptom severity. Open trials of selective serotonin reuptake inhibitors have been conducted and suggest that these and similar agents show promise for the reduction of complicated grief symptom severity, but randomized placebo-controlled trials are needed before more definitive conclusions can be drawn about their efficacy for the amelioration of complicated grief symptomatology.

Future pharmacotherapeutic options may also evolve from ongoing studies of functional neuroanatomy. In one study, grieving subjects were exposed to visual and verbal stimuli to remind them of the deceased. The stimuli led to activation in the posterior cingulate cortex, cerebellum, and medial/superior frontal gyrus. Thus, grief is mediated through a complex network involving affect processing, visual imagery, autonomic regulation, memory retrieval, processing of familiar faces, and modulation/coordination of these functions. New insights into the long-term health consequences of grief may follow, as well as therapies to modulate the neurochemical response.

As mentioned previously, a lack of social support is a significant risk factor for the development of complicated grief. Thus, it follows that bereaved individuals who lack a social network may be helped greatly by group therapy and support groups. Studies show that the perception of social support leads to a reduction of depression, whereas group therapy for complicated grief leads to an increase in perceived support.

One therapy specifically developed for complicated grief is known as complicated grief treatment. This combines a number of different approaches, including psychoeducation about normal grief and complicated grief, a dual focus on adjusting to the loss and restoration of a satisfying life, and motivational therapy to create appropriate life goals. This therapy was found to be more effective in a shorter time than interpersonal psychotherapy in a population of complicated grief patients. However, given the eclectic nature of the treatment, it is difficult to discern which specific component is providing the main benefit. Using a model in which grief is conceptualized as trauma, the therapy also includes desensitization through imagined conversations with the deceased, retelling of the death scene, and viewing photographs of the deceased. For nontraumatic deaths, however, this aspect of the treatment may be less important than dealing with issues of attachment, separation, loss, and reattachment.

Further research will yield insight into the most effective therapies for bereaved people suffering from

overwhelming grief symptoms. Most important, an understanding of complicated grief will encourage clinicians to help prepare caregivers of terminally ill patients for their loss. Providing appropriate resources before the loss will better facilitate normal grieving and grief resolution and ensure that survivors can more successfully adapt and resume a functional and joyful life.

Rationale for Group Therapy
Therapeutic Elements of Group Therapy
Applications
Conduct of Group Therapy

Glossary

Abreaction

A process by which repressed material, particularly a painful experience or conflict is brought back into consciousness. In the process, the person not only recalls but relives the emotional situation and experiences the appropriate emotional response.

Catharsis

The verbalization of ideas, thoughts, and expressed material that is accompanied by an emotional response and that produces a state of relief to the individual.

<i>Corrective recapitulation of the primary family group</i>	The phenomenon that patients in a therapy group relate to the group leaders and other members in ways reminiscent of how they once interacted with their parents, siblings, or other significant figures as they grew up; also called family reenactment.
<i>Counter-transference</i>	Reactions evoked in the therapist in response to the patient. These feelings, conscious or unconscious, may be realistic or arise from unresolved pathology. They are regarded as analogs of the patient's transferences.
<i>Group debriefing</i>	An intervention and stress management technique in which the major elements of a trauma are reviewed by participants in an attempt to prevent or reduce the immediate or long-term adverse psychological changes. Although it is therapeutic, is conducted in a group setting, and employs many principles and techniques of group therapy, group debriefing is not truly group therapy. It may proceed to group therapy if the members request that meetings continue because of persistent symptomatology and both the leader and members agree to further sessions.
<i>Group facilitator</i>	A support or educational group leader who assists the group in maintaining its boundaries, keeps the group on task, and provides group feedback by sharing observations and summarizing the process of the group with its members. The intent of the facilitator is not to attempt individual personality changes but to encourage self-learning, attitudinal shifts, and stress reduction.
<i>Group therapist/leader</i>	The most important person in the group; responsible for selecting and preparing patients, forming the group, and conducting the group in a manner that models ideal group behavior and creates therapeutic group norms to enable its members to attain their therapeutic goals, which may involve personality and behavior changes.
<i>Group therapy</i>	A widely accepted psychiatric treatment modality that uses therapeutic forces within the group, constructive interactions between members, and interventions of a trained leader to change the maladaptive behavior, thoughts, and feelings of people with a psychiatric disorder.
<i>Repression</i>	The unconscious act of controlling and inhibiting an unacceptable impulse, emotion, or thought.
<i>Suppression</i>	The conscious act of controlling and inhibiting an unacceptable impulse, emotion, or thought.

<i>Transference</i>	In the classic sense, all aspects of a patient's feelings and behavior toward a therapist, including rational and irrational aspects that arise from unconscious sources; usually classified into positive and negative reactions. In the general sense, it includes real aspects of the relationship and the unconscious influences of parental or other meaningful figures early in the individual's development.
<i>Universality</i>	The experience by the patient in a group setting that he or she shares many similarities and features in common with others, that "We are all in the same boat."

Rationale for Group Therapy

Some of the principles of group therapy have been applied with success in the fields of business and education in the form of training, sensitivity, and encounter groups. Individuals participating in such groups are generally not regarded as having a psychiatric disorder. Group therapy is also used in the prevention of psychiatric illness, and some of its tenets are applied in debriefing formats for acute stress reactions. Because of the numerous forms of group therapy, it is more accurate to speak of the many group therapies. However, for the sake of simplicity, it should be understood that the generic term group therapy in this article is used to describe a wide array of treatments in a group setting with their particular requirements and different objectives and goals.

Treatment in groups is a proven and effective therapeutic modality for stress-related conditions. Historically, the group has served as a protector and nurturer of the individual and a purveyor of culture. Although originating in the United States in 1905, group methods were initially used by English psychiatrists who were under pressure to treat the vast number of psychiatric casualties suffering from stress and trauma during World War II. In the safe environment of the group, patients or members have the opportunity to interact with others in a setting reflective of society at large; to gain mutual support; to be exposed to new learning situations; to express and benefit from altruism, which in itself can be beneficial; and to find opportunities for multiple healthy identifications and catharsis. In the group, a here-and-now focus and interpersonal relationships are stressed more than in individual therapy.

Therapeutic Elements of Group Therapy

Numerous conceptual models of group therapy exist, but they share in common certain therapeutic

elements or factors that have been studied and found to be curative for individuals in groups. More than 200 group process and therapeutic elements have been described in the literature to account for the curative changes that occur in group therapy. These can be classified into the broad categories of intellectual, emotional, and action factors. One of the most widely accepted classifications identifies 11 primary elements: the installation of hope, universality, the imparting of information, altruism, the corrective recapitulation of the primary family group, the development of socializing techniques, imitative behavior, interpersonal learning, group cohesiveness, catharsis, and existential factors. The therapeutic factors, are frequently interdependent and share similarities.

Not all of these curative or therapeutic factors need to be present for the group to be effective. Certain types of groups require the presence of particular elements. For example, in groups dealing with stress disorders arising from an acute or immediate traumatic event, emphasis is placed on imparting information, abreaction, catharsis, and universality. When the stress has been chronic and caused conditions of a chronic nature, there is a greater focus on interpersonal learning, the corrective recapitulation of the primary family group, and the development of socializing techniques, in addition to the aforementioned factors. In the latter setting, transference and countertransference are more likely to occur.

Types of Groups

Group therapy is used in inpatient and outpatient settings, institutional work, partial hospitalization units, halfway houses, community settings, and private practice. Open-ended groups exist for an indefinite time period, are open to new members, and pursue a variety of therapeutic goals. Closed-ended groups are time-limited, closed to new members, and focus on achieving a particular goal or purpose. Time-limited groups, or short-term groups, are commonly employed to treat people with acute stress-related disorders. The duration of treatment is ordinarily stated at the start of the group and rarely exceeds several months. Individuals exposed to a traumatic or catastrophic event may be seen for only one group session.

Placement in a long-term group is usually indicated for patients who have experienced chronic stress from underlying medical conditions or needing to reduce chronic stress that may contribute to the formation of physical or emotional illnesses. Long-term groups typically run for several months to several years and convene at regular and frequent intervals such as once or twice weekly.

Group Size

The size of the group varies considerably in the treatment of stress-related conditions. When a catastrophic or traumatic event involves a large number of people, debriefing groups may have as many as 100 or more people, whereas a therapy group for posttraumatic stress disorder (PTSD) patients usually consists of 5–10 members. Generally, smaller groups are more appropriate for an intensive and prolonged group therapy experience.

Group Composition

Individuals placed in a group setting for the treatment or prevention of psychiatric symptoms or illness in which stress plays a prominent role are admitted on the basis of their primary symptom (such as phobias, anxiety, or depression), an illness or diagnosis (such as PTSD; cancer; or human immunodeficiency virus, HIV), or an event (such as rape, surviving the Holocaust or a concentration camp, or a recent disaster). Although secondary considerations of age, gender, socioeconomic, and ethnic factors are of lesser importance in stress-related groups than in traditional group therapy, a compatible matching of these elements may ensure greater success for the individual and the group.

Applications

Group therapy is useful for people who have experienced a vast number of situations or medical conditions in which stress plays a major role. Some examples include PTSD patients, sexual or physically abused victims, concentration camp survivors and their families, bereaved people, cancer patients, and family members and caretakers of patients with chronic mental or physical illnesses. There are established groups for patients with HIV and acquired immunodeficiency syndrome (AIDS), with chronic fatigue syndrome, with ulcerative colitis, with heart disease, with diabetes, with obesity, with fibromyalgia, and on long-term dialysis. The list is varied and growing.

Conduct of Group Therapy

The basic principles of group therapy are observed in most therapy groups, although the approach varies with the type of group that has been formed in response to the specific situation. A few of the common approaches and indications for group treatment are described next.

Group Debriefing

Perhaps the most widely known and used intervention to treat individuals exposed to acute traumatic situations, the aims of group debriefing are to manage the immediate emotional distress and to prevent adverse long-term psychological changes. There are several debriefing protocols; one of the best known and most widely practiced is the critical incident stress format developed by J. Mitchell in 1981. The protocol consists of consecutive phases in which various aspects of a traumatic exposure are explored and worked through by the participants. The focus remains on the individual and not on the group. Members are encouraged to recall their personal experiences of the traumatic event to allow for ventilation and to attempt to understand and master the confusion and trauma. Education and the mobilization of social support are key elements in this approach, and symptomatic individuals are identified and referred for further treatment. Some of the goals of debriefing are to assist individuals to regain emotional and cognitive controls; reduce cognitive dysfunction; diminish traumatic conditioning; and reduce group scapegoating, projection, and nihilistic and antisocial attitudes that may arise in response to the trauma and to correct improper information about the event. Debriefing is usually conducted in naturally occurring groups, is considered short term, lasting at most only a few sessions. Because this approach has the potential to produce negative outcomes as well as positive results, it is essential that the leader or leaders be well trained in group work.

Cancer Groups and Groups for the Terminally Ill

Depending on the nature of the illness and prognosis, cancer and terminally ill patient support groups may be short or long term and open- or closed-ended. Breast cancer group therapy has been the best researched of the group approaches and in many studies it has been shown to increase the length and quality of patients' lives. Patients suffering from terminal cancer experience significant stress in attempting to deal with their anguish, loss of control over what is happening to them, physical pain and disability, and sense of uselessness while awaiting death. Through the group experience, they are afforded the opportunity to find meaning outside themselves and provided a sense of purpose as they support one another and share their life experiences.

Patients in the terminal stage of cancer frequently harbor irrational and rational anger toward their families, the helping professions, and society in general. The group experience often assists them to transcend their immediate plight to find a deeper meaning for their existence and to accept death with greater

equanimity. Similarly, the caretakers of these patients who are members of cancer support groups derive emotional support and gain helpful information from others to reduce their stress levels and to deal with the resentment, guilt, and anger that may develop in the course of caring for terminally ill relatives.

The hypothetical 5-year waiting period during which no evidence of recurrence has been found and a cure is likely is a stressful time for many post-treatment cancer patients. Group therapy for these recovering patients may be long term and supportive in nature as individuals share medical information, personal setbacks, and coping strategies. For many members, it is a time for personal growth and maturation as they struggle with their illness and the impact it has had on their lives.

The main therapeutic elements present in successful cancer groups appear to be group cohesion, social support, enhancing communication skills with family and health-care workers, relaxation training, and the opportunity for emotional expressiveness.

Support Groups for Other Medical Conditions

Group therapy has been useful for a wide array of medical illnesses that are partially caused or aggravated by stress. In turn, stress may arise as a consequence of suffering with a medical illness. Most of these groups are open-ended, long term, and meet on a regular basis. Many of the therapeutic elements found in cancer support groups are also present in these groups. Major emphasis is placed on imparting information, learning coping skills, social support, the installation of hope, and dealing with here-and-now situations. Unlike those in cancer support groups, the patients in these groups may not face imminent death despite the chronicity and severity of their illnesses.

Posttraumatic Stress Disorder Groups

Group therapy is one of the most widely used treatments for patients with PTSD. Individuals diagnosed with acute PTSD, in which the symptoms have been present for less than 3 months, may be treated successfully in a time-limited or short-term group. Individuals showing symptoms of a chronic PTSD generally require long-term treatment.

In the various group therapies used for patients with these disorders, the goals and objectives are to contain their severe distress and suffering and to improve the quality of their lives. To attain these ends, a variety of group approaches are employed, ranging from a cognitive behavioral focus to the use of psychodynamically oriented psychotherapy. The behavioral model emphasizes the reduction of symptoms, the acquisition and maintenance of coping skills, and

the systematic examination of the assumptions and misattributions that govern the patient's behavior, expectations, and appraisal of events (as described in the works of Foa and colleagues in the 1990s). Prominent in these groups are the mechanisms of group cohesiveness, imparting of information, imitative behavior, interpersonal learning, and installation of hope.

Since the 1970s, Horowitz and his colleagues have researched and firmly established that a psychodynamically oriented approach is successful in the treatment of PTSD. The goal for the traumatized patient is to reconcile the occurrence of the trauma with his or her personal concept and the world. The principal aim of this therapy is to assist individuals to integrate their traumatic experiences through the therapeutic reexperiencing of the events in a supportive environment. Attempts are made to gain insight into the conscious and unconscious meaning of the symptoms to enable patients to master the trauma and restore functioning. This approach acknowledges the influence of dispositional variables on the patients' response to the trauma and therapy and emphasizes the use of the corrective recapitulation of the primary family group, interpersonal learning, insight, and catharsis more than other types of group treatments for stress.

Staff and Caretaker Support Groups

Because of a heightened awareness of dementias, especially Alzheimer's disease, the increasing longevity of the world population, and the large numbers of the chronically mentally and physically ill, participation and interest in staff and caretaker groups have grown significantly. Typically, health-care providers and caretakers operate under high and sustained daily levels of stress, and they benefit from participation in a group. The emphasis on these groups is to enable individuals to provide better patient care and smoother functioning in their surroundings through improved staff well-being. The groups are usually conducted by a facilitator instead of a group therapist or leader, and the goals and objectives are to assist members in reducing stress rather than to explore personal conflicts or to attempt personality change. Group meetings may occur weekly, on an ad hoc basis, or for a set number of sessions in defined modules over the span of a year.

Benefits gained from participating in the group experience include decreased anxiety, reduced sense of isolation, more open communication between caregivers, increased self-esteem, improved adaptation in working with patients or ill family members, and greater group cohesion and teamwork.

Scapegoating and irrationality diminish, patient-care goals become more realistic, and staff members are better able to tolerate and accept pain and suffering in their patients without feeling excessive personal distress.

Concentration Camp and Torture Survivor Groups

A large number of Holocaust survivors exist in the world, with Israel alone housing over 250,000. In addition to Holocaust survivors, there are concentration camp survivors from the Bosnia-Herzegovina war and survivors of torture from Central and South America and nations in Africa. Many elderly Holocaust survivors manifest the survivor syndrome, typically, reporting anxiety, sleep disorders, affective disturbances, and survivor guilt. As these individuals age, their symptoms intensify because of economic and health problems and because of the constant reminder of their previous plight due to the unstable world situation with reports of internment camps, torture, terrorism, and serious religious and ethnic conflicts. Exiled survivors of torture must deal with the acute trauma, loss of family or close ones, often forced migration, and adaptation to a new culture.

Group therapy is supportive in nature and attempts to help survivors cope with the anxieties and painful memories that are still fresh or have been rekindled by disturbing world events, work through the mourning for lost relatives and their own personal losses, improve their mental equilibrium, and enhance their adaptation to their inner and outer worlds. A major objective is to create a sense of safety and well-being in the groups so patients can express themselves freely. Attempts are made early in therapy to create supportive group interpersonal relationships with active leader interventions to help members integrate their painful past with current joys and successes in the present. Many of these groups are open-ended both for membership and in duration because rarely are these individuals able to completely set aside what has happened to them and to successfully proceed in life without a periodic resurgence of disturbing symptoms.

Rape and Sexual Abuse Victims Groups

Victims of rape and sexual abuse typically experience effects on body image, identity, self-regulation, and interpersonal functioning. If the abuse has occurred in childhood and is ongoing, these areas may be affected profoundly. Victims experience both acute and chronic stress when reminded of the trauma, and they are frequently conflicted in their social and sexual relationships. Group therapy helps victims through the reenactment of the traumatic situation and abuse

in the confines of a safe environment, increases their capacity for self-soothing, deals therapeutically with the shame, and teaches patients how to end the cycle of repeated victimization.

The therapeutic or curative factors of universality, interpersonal learning, catharsis, developing socializing techniques, and imparting information are prominent in the group processes. The groups may be short or long term, depending on the acuity of the situation. These groups are often open-ended to accommodate newcomers and to allow previous members to return for periodic reinforcement and support of their newly acquired knowledge and behaviors. Psychoeducation is provided in these groups to instruct patients about abuse effects, in developing problem-solving skills, and in becoming active in supportive topic-focused discussions.

In summary, group therapy or a group therapeutic approach is an effective modality in the treatment of acute and chronic stressful conditions. Indications for group therapy mirror those for individual approaches; but the group has as an advantage the presence of group therapeutic or curative factors not present in individual therapy. The group becomes a safe haven and laboratory where members learn from one another, practice new behaviors in a supportive setting, and are provided opportunities to show altruism, which in itself is a constructive healing force. The group serves as a microcosm of society from which members can venture forth again into the larger society with new knowledge and personal gains from the group experience.

Some individuals find it difficult, if not impossible, to develop sufficient trust and the sense of confidentiality in a group setting, and they may require an introductory period of individual care before introducing them to group therapy. In addition, individuals may benefit from a combination of concurrent individual and group approaches to test out new behaviors and learning.

Perpetrator Groups

Perpetrator groups are gaining in popularity with the increase in public awareness about sexual predators and about emotional and physical abuse in relationships. Common in institutional and court-directed settings, many are now present in both community and private locations. Individuals are afforded a safe environment for catharsis, to sense their impact on others with similar backgrounds, to gain understanding into their behavior, and to learn techniques to control and modify their destructive behavior. These groups tend to be long term and open-ended, and they may employ treatment principles found in alcohol

and substance abuse groups. Anger management techniques and psychoeducation also play important roles.

Glossary

Acetylcholinesterase (AChE) inhibitors Chemical agents capable of preventing the enzyme acetylcholinesterase from performing its catalytic function, namely, the hydrolysis of acetylcholine. These inhibitors may vary in their chemical structure and include natural compounds, drugs, commonly used insecticides, and chemical warfare agents.

Alternative splicing A molecular process through which a single gene may produce more than one protein with distinct properties.

Blood–brain barrier (BBB) The complex structures and processes that prevent the free penetration of compounds into the brain (and free exit from it). It includes the epithelial cells lining the walls of blood vessels in the brain and the end foot of astrocytes surrounding these blood vessels. The tight junctions between endothelial cells in brain blood vessels are major players in this function, as are several proteins and active pumps controlling the move of compounds in and out of the brain.

Psychological stress An emotional state of anxiety and hyperexcitation that may have various origins

and causes and that varies in intensity. It probably is important to ensure rapid, alert functioning under external insults; however, it may also cause delayed adverse consequences at different levels and functions.

Transgenic overexpression

The excessive production of a foreign protein in the cells and tissues of an organism that has been made transgenic by the introduction of foreign DNA into its genome. The transgene included in this DNA directs the production of its protein product in the host organism, leading to overexpression because it is produced in addition to the normal functioning of the host gene.

Acute Psychological Stress and Exposure to Anticholinesterases Cause Similar Delayed Effects

Posttraumatic stress disorder (PTSD) involves delayed cognitive deterioration, depression, irritability, and persistent deficits in short-term memory, as summarized by Robert Sapolsky in 2003. Stress-induced changes in nervous system structure and function appear in many diverse species, suggesting that they reflect an evolutionarily conserved adaptation to environmental insults. For example, magnetic resonance imaging (MRI) demonstrates reduced hippocampal volume in PTSD patients.

Surprisingly similar effects are often reported years after acute or chronic exposures to cholinesterase inhibitors. The use of the carbamate anticholinesterase (anti-AChE) pyridostigmine during the Gulf War for prophylactic protection under threat of chemical warfare emphasizes the importance of this topic, as does the increasing use of anti-AChE drugs for the treatment of Alzheimer's disease. [Table 1](#) summarizes these reports.

Neurophysiological stress events are initiated by millisecond-long bursts of neurotransmitter release, whereas the long-term, persistent brain changes occur at a very slow pace, sometimes over years. Moreover, stress responses primarily elicit hormonal modulations in peripheral tissues, and ACh controls inflammatory reactions. Yet, it is not clear how this imprints on brain structure and function in a long-delayed manner. Finally, the link between structural and functional properties in the brain itself calls for an

Table 1 Common outcomes of psychological stress and anticholinesterase exposure^a

	<i>Organism</i>	<i>Inducer</i>
<i>Neuropathological phenomena</i>		
Excessive sprouting and retraction of neuronal processes	Mollusk	Variety of stressors
Decreased density of dendritic spines, where synaptic connections take place	Transgenic mice overexpressing AChE	Cage life
Atrophy of apical dendrite in the hippocampus region CA3	Tree shrews (primate)	Restraint stress
Reduced hippocampal volume	Humans (war veterans)	Acute traumatic war experience
Degenerative changes in the spinal cord	Hens	Low-level exposure to the organophosphate anti-AChE leptophos
Degeneration of the hippocampus	Rats	Low-level exposure to the organophosphate anti-AChE fenthion
Arrest of neuronal proliferation	Primates (rhesus)	Sociological stress
<i>Impaired functioning</i>		
Enhanced long-term depression of hippocampal activity	Rats	Mild behavioral stress
Enhanced long-term depression and suppressed long-term potentiation of hippocampal activity	Rats	Restraint stress and electric tail shock
Increased permeability of the blood–brain barrier	Mice	Forced swimming stress, transgenic AChE overexpression
Behavioral changes	Primates (<i>Callithrix jacchus jacchus</i>)	Psychological stress
Deficits in short-term memory, long-term psychopathologies	Humans	Combat-related stress, childhood abuse
Impaired firing of CA1 neurons in the hippocampus	Rabbits	Acute exposure to the organophosphate anti-AChE parathion
Suppressed long-term potentiation in the hippocampus	Rats	Acute exposure to the organophosphate anti-AChE soman
Memory impairments	Rats	Low-level exposure to the organophosphate anti-AChE DFP or phosphorodithioate
Increased permeability of the blood–brain barrier	Rats	Soman intoxication
Deficient cognitive performance	Rhesus monkeys	Soman intoxication
Progressive deterioration of memory and general cognitive decline	Humans	Organophosphate pesticide poisoning
Intensified traumatic memories	Mice	Immobilization stress

^aLong-term consequences of psychological insults and anticholinesterase exposures in various evolutionarily remote species. Note the similarities in the nature of the changes observed in both the structural and functional properties of neurons. AChE, acetylcholinesterase; DFP, diisopropyl-fluorophosphonate.

in-depth study of the causal relationships leading to these changes.

The Blood–Brain Barrier Is Disrupted under Stress

Several studies have demonstrated enhanced penetration of the brain by anti-AChEs under psychological stress. This stress-induced disruption of the BBB can explain some of the nervous system-associated sequelae reported by Gulf War veterans. Soldiers at the Gulf were exposed to unknown doses and combinations of various harmful xenobiotics. For prophylactic protection from the anticipated chemical warfare agents, which would have irreversibly blocked acetylcholinesterase (AChE), Gulf War soldiers were administered pyridostigmine, a reversible carbamate cholinesterase inhibitor. Pyridostigmine includes a quaternary ammonium group that under normal circumstances prevents its crossing the BBB. Thanks to this property, it is used routinely to treat peripheral neuromuscular

junction deficiencies in patients with the autoimmune disease myasthenia gravis. During peacetime clinical tests that involved healthy volunteers, pyridostigmine caused mild, primarily peripheral side effects. In contrast, during the Gulf War, pyridostigmine in the same dosage caused a significant increase in reported central nervous system (CNS) symptoms. Friedman and colleagues showed, in animal experiments, that the dose of pyridostigmine required to block 50% of brain AChE was 100-fold lower in stressed mice.

The sudden need for energy in the stressed brain suggests that the disruption of the BBB may be beneficial when neurons are overactivated. Nevertheless, BBB disruption may also allow toxic agents and unneeded proteins to penetrate the brain, which may impair brain functioning under stress. However, the linkage between neuronal excitability and the nature of those impairments is still largely obscure. AChE inhibitors, which increase cholinergic signaling by preventing acetylcholine (ACh) hydrolysis, were reported to cause transient permeabilization of the

BBB. Revealing the molecular mechanisms underlying the links between cholinergic and other elements in BBB-associated cells should therefore contribute significantly toward our understanding of the mechanism(s) leading to BBB disruption under psychological stress. Because cholinergic neurotransmission is imbalanced following traumatic impacts, this question was addressed using transgenic mice overexpressing synaptic AChE. Diffusion-weighted MRI showed impaired water diffusion and BBB functioning, and DNA microarray analyses demonstrated the enhanced production of multiple ion channels and the water channel aquaporin 4. Thus, persistent cholinergic imbalance may by itself cause BBB malfunctioning.

Early Immediate Response Genes Modulate Acute Stress Signals

The similar symptoms reported for patients with PTSD and those exposed to anti-AChEs pointed to ACh as the common inducer of these delayed responses. Several pieces of evidence support this conclusion.

1. Robust elevations of ACh levels occur under both PTSD and anti-AChE intoxication.
2. ACh interaction with an ACh receptor(s) elevates intracellular Ca^{2+} levels, inducing the transcription of genes that have promoters with Ca^{2+} response elements (CRE motifs).
3. One of these Ca^{2+} -induced genes encodes the early immediate transcription factor *c-Fos*. Interestingly, *c-Fos* expression is elevated drastically within minutes under stress.

Both the choline acetyltransferase gene, *ChAT*, and the AChE gene, *ACHE*, are subject to stress-induced regulation. The first intron in the *ChAT* gene includes the coding sequence for the vesicular ACh transporter VACHT. Together they form the cholinergic locus. Therefore, these two mRNA transcripts are coregulated, and the early immediate gene (IEG) *c-Fos* can control both the initiation and the termination of cholinergic neurotransmission. This operates through regulating ACh production by *ChAT*, its vesicle packaging by VACHT, and its hydrolysis by AChE. Measurements of mRNA levels in conjunction with neurophysiology tests have indeed demonstrated the suppression within 3 h of the initial cholinergic hyperexcitation, most likely through the suppression of ACh synthesis (through decreases in *ChAT* and VACHT mRNA levels) and the enhancement of its hydrolysis (through increases in AChE mRNA levels) within 30 min postinsult. However, the association of stress processes with the bimodal suppression of the initial increase in released ACh does not tell us how

specific *c-Fos* dimers sort out their respective promoters to induce the observed opposing effects. Moreover, it is not clear how much of the increased intracellular Ca^{2+} is due to influx through specific channels in the plasma membrane and how much of it results from Ca^{2+} release from intracellular stores. In addition, other IEGs may also contribute to the observed phenomenon. For example, the activation of muscarinic cholinergic receptors induces multiple IEGs. Also, the time scale of the Ca^{2+} -induced transcriptional response should be refined. Most important, the initial phase of the feedback response probably leads to delayed cascades of the transcription of other relevant genes, and both the scope and the nature of these secondary phenomena are still unknown.

Hypothalamic-Pituitary-Adrenal Involvement in Acute Stress Responses

Stress-induced activation of the hypothalamic-pituitary-adrenal (HPA) axis enhances the release of adrenocorticotrophic hormone (ACTH) from the hypothalamus and of corticosterone from the adrenals. Corticosterone, in turn, stimulates the production of several cytokines, among them interleukin (IL)-1, tumor necrosis factor (TNF), and IL-6. Tracey and colleagues have found that ACh controls the production of pro-inflammatory cytokines by tissue macrophages. This suggests that AChE overproduction and the resultant reduction in ACh levels induce an increase in the inflammatory reactions, as summarized in [Figure 1](#). Thus, the capacity for AChE overproduction under stress affects both peripheral and brain-mediated responses. When produced in the brain, IL-1 interacts with IL-1 type I and type II receptors. This induces *c-Fos* overproduction, which further potentiates the peripheral production of steroid hormones. Therefore, many responses evoked by stress depend on the activation of the HPA axis, are prevented by adrenalectomy, and can be mimicked by exogenous corticosterone (or cortisol in humans). Glucocorticoids induce increases in intracellular Ca^{2+} within the hippocampal neurons, inducing neurotoxic effects in the brain, mainly atrophy and degeneration of hippocampal neurons that are enriched in glucocorticoid receptors. Brain endothelial cells also express IL-1 receptors, suggesting a link between this cytokine, the BBB, and the HPA axis.

Not all stress responses are totally dependent on adrenal functions. An example is the cholinergic feedback response to stress and anti-AChEs described earlier, which apparently includes an HPA-independent component. This is supported by the following:

Figure 1 Cholinergic reactions to stress. a, Acetylcholinesterase (AChE) and acetylcholine (ACh) balance determines the cholinergic signaling status; b, cholinergic excitation modifies the alternative splicing of AChE-mRNA transcripts; c, origins of risk factors affecting stress reactions; d, links among stress, cholinergic signaling, and inflammatory reactions. In b, cholinergic synapses are presented as glass beakers, with ACh inflow shown as the top taps and ACh outflow as water streaming out. Impaired splicing (i.e., accumulated synaptic AChE-S) potentiates the outflow, whereas protective splicing (production of AChE-R) maintains balanced flow. When mimicked in transgenic mice, impaired splicing exacerbates stress neuropathology, whereas protective splicing ablates it. In c, a schematic graph shows inherited, experience-derived (e.g., increased body mass index), and environmental measures (e.g., insecticides exposure) affecting the level of risk for stress-induced damages. In d, stress induces ACh release, which induces a shift from synaptic AChE-S to the stress-induced AChE-R splice variant. The excess AChE reduces ACh, which relieves the control over production by tissue-residing macrophages of pro-inflammatory cytokines. Therefore, AChE-R levels are associated with those of pro-inflammatory cytokines (stars). AChE-R, readthrough variant of acetylcholinesterase; AChE-S, synaptic form of acetylcholinesterase; IL, interleukin; TNF α , tumor necrosis factor α .

1. Acute ACh release and its delayed suppression occurred in adrenalectomized rats.
2. Stress-induced overproduction of *c-Fos* mRNA occurs in adrenalectomized mice.
3. The transcriptional feedback response occurs in brain slices.
4. Transgenic mice with a cholinergic, but not HPA, imbalance show impaired BBB and stress neuropathology.

Altogether, this information calls for further research into the specific contributions of the HPA and internal brain processes to the cholinergic feedback response.

Poststress Changes Are Long-Lasting

Alternative splicing produces three AChE isoforms. Of these, the readthrough variant (AChE-R) encodes

a hydrophilic enzyme form secreted as a globular monomer following stress events. The amphiphilic soluble properties of the stress-induced AChE isoform may provide easy accessibility to extracellular spaces flooded under stress with excess ACh. This form of the enzyme is therefore best suited for suppressing the activation of ACh receptors that is associated with stress or anti-AChE exposures.

Biochemical analyses of catalytically active AChE demonstrated that globular monomers are produced following treatment with diisopropylfluorophosphate (DFP; a potent AChE inhibitor) and in the cerebrospinal fluid (CSF) of Alzheimer's disease patients.

In the nonstressed brain, AChE mRNA is positioned around the nucleus of cortical neuronal somata. Following stress or under anti-AChEs, AChE-mRNA appears throughout the cell body, extending to prolonged dendrites. Intracellular changes in the

distribution of mRNAs are often associated with modified functions of their protein products. Therefore, Meshorer and coworkers postulated in 2002 that this altered localization may be physiologically significant.

The poststress accumulation of AChE takes place primarily in cholinceptive brain regions involved in learning and memory, such as the cortex and the hippocampus. The accumulation of the enzyme in the hippocampus is relatively short-lived (a few hours). This suggests the cessation of the poststress AChE-mRNA transcription (or the enhanced degradation of AChE-mRNA or protein) in brain regions that extend cholinergic afferents to the hippocampus. In contrast, cortical AChE levels remain significantly elevated over 3 days poststress. This may reflect continuous local production in cortical cholinergic interneurons. The initiation of CNS stress responses can thus lead, within milliseconds and continuing for several days at least, to AChE excess in the mammalian cortex. Interaction of the stress-induced AChE with signaling kinases can explain the changes induced in neuronal functioning.

Acetylcholinesterase Accumulation Confers Protection against Anticholinesterases

The accumulation of brain AChE increases the concentration of binding sites for anti-AChEs. For

example, Kaufer et al. demonstrated in 1998 that pyridostigmine doses that reduce body temperature in normal, untreated FVB/N mice have no effect when administered 24 h after stress treatment. Similarly, transgenic mice overexpressing AChE in their brain neurons also display resistance to the hypothermic response to pyridostigmine. This supports the conclusion that the stress-induced resistance to anti-AChEs is due to AChE accumulation because elevated AChE levels persist in the brains of these mice. Pyridostigmine protects against the lethal effects of chemical warfare agents that are anti-AChEs. The protection conferred by pyridostigmine may therefore be related, at least in part, to AChE overproduction that is induced by pyridostigmine during the first few hours following treatment.

Acetylcholinesterase Gene Expression Associates with State and Trait Anxiety

Recent genotype–phenotype interaction studies support the notion of AChE interactions with stress responses. In the U.S. population, volunteers with polymorphisms debilitating the functioning of the *ACHE* gene or the adjacent paraoxonase *PON1* gene on the long arm of chromosome 7 were found to display increased trait anxiety or the tendency for state anxiety, as shown in Figure 2.

Figure 2 Association of AChE and PON variations with state and trait anxiety. a, Gel electrophoresis of serum samples from volunteers with high or low trait anxiety; b, the putative genomic link; c, age-dependent changes in the capacity for AChE overproduction ($R^2 = 0.73$). In a, note that subjects with low anxiety show more AChE monomers (M) than those with high anxiety, although tetramers (T) and dimers (D) remain unmodified ($N = 472$ volunteers). Thus, the alternative splicing process yielding AChE-R monomers links to trait anxiety. In b, the *ACHE* and *PON1* genes are positioned close to one another on the long arm of chromosome 7. Exposure of AChE to organophosphate inhibitors (OP) inhibits its activity by forming irreversible AChE–OP complexes. This induces a feedback response leading to AChE overproduction. However, paraoxonase (PON) degrades OPs, thus protecting the AChE protein. In addition, PON functions as a peroxidase, protecting blood proteins (AChE included) from oxidative stress. In c, blood AChE levels increase by over 25% between the ages 15 and 66, suggesting a progressive limitation in the capacity for stress-induced AChE overproduction (arrows).

Delayed Nervous System Deterioration under Persistent Acetylcholinesterase Overexpression

Apart from its capacity to hydrolyze ACh, the AChE protein possesses other, noncatalytic activities. These are apparently related to neurite extension in cholinergic as well as dopaminergic neurons and are fully sustained in genetically inactivated AChE. This suggests that the structural effects of AChE might also operate when the AChE protein is inactivated catalytically by anti-AChEs. The long-term outcome of neuronal AChE excess was studied in patients with the autoimmune disease myasthenia gravis and in rats with experimental autoimmune myasthenia. In both cases, the chronic overproduction of AChE-R was observed. Antisense oligonucleotide suppression of this excess enzyme improved neuromuscular functioning in treated rats. Parallel outcomes in clinical trials was reported at the U.S. Society of Neurology in 2004. In the neuromuscular junctions of AChE transgenic mice (the synapses connecting motor neurons with the innervated muscle), impaired

neuromuscular transmission was observed. Similar phenomena were reported for patients with neurodegenerative or neuromotor syndromes associated with cholinergic malfunction, such as Down syndrome, Alzheimer's disease, and myasthenia gravis. Indeed, Farchi and co-workers reported the deterioration of the physiological responses of AChE transgenic muscle, reminiscent of those of myasthenia patients.

Exposure to agricultural insecticides, which serves as a case study for the risks involved in exposure to chemical warfare agents, also increases the risk of Parkinson's disease. It was known for several decades that this risk also involves predisposing genotype-phenotype elements. In a study performed in Israel, this increased risk was found to be associated with debilitating polymorphisms in the *ACHE* and the *PON1* genes. Exposed patients showed an increased incidence of such debilitating polymorphisms, suggesting that an inherited interactive weakness of AChE and *PON1* was the cause. These findings, reported by BenMoyal-Segal and co-workers, are schematically presented in Figure 3.

Figure 3 Risk-associated *ACHE/PON1* polymorphisms are strongly overrepresented in exposed Parkinson's disease (PD) patients. a, The *ACHE/PON1* locus; b, the *PON1* protein and frequent polymorphisms; c, graphs of increased incidence of debilitating *ACHE/PON1* haplotype in insecticide-exposed Parkinson's patients; d, the AChE protein and its interaction with paraoxon. In a, a diagram of the adjacent *ACHE* and *PON1* genes is shown, with the tested nucleotide polymorphisms marked below. The two debilitating polymorphisms found frequently in patients with Parkinson's disease who were continuously exposed to agricultural insecticides are circled. In b, the crystal structure of paraoxonase is shown with the two frequent changes in it, in positions 55 and 192. Note that *PON1* interacts with blood lipids (HDLs). The paraoxon binding site is circled. In d, the crystal structure of the AChE protein is shown. Paraoxon is circled in its deep-buried binding site, where its binding blocks AChE functioning irreversibly. Star indicates a statistically significant difference in the incidence of the debilitating *ACHE/PON1* polymorphisms within insecticides-exposed Parkinson's disease patients. C/Δ, carriers of the robust *PON1* and the debilitated AChE variant; C/wt, carriers of the two robust variants; HDL, high-density lipoprotein; T/Δ, carriers of the two debilitated variants; T/wt, carriers of debilitated *PON1* and robust AChE.

Retrospective and Prospective Implications

The feedback response to acute stress and anti-AChEs apparently varies in its intensity with age, body mass index, gender, and ethnic origin. Homozygous carriers of mutations in the *ACHE* homologous *BCHE* gene, encoding serum butyrylcholinesterase (BCHE; e.g., the atypical variant), have anomalous responses to cholinergic drugs. In such individuals, relatively low doses of anti-AChEs may penetrate the brain quite effectively, which results in higher effective doses than intended. This creates a genetic predisposition to adverse responses to anti-AChEs. This inherited sensitivity, and the findings already summarized, raise a concern with regard to the long-term dangers of chronic exposure to household and agricultural insecticides because these are frequently organophosphate or carbamate anti-AChEs. Moreover, the partial symptomatic relief offered by the currently approved Alzheimer's disease anti-AChE drugs appears to be limited in its duration, suggesting that the feedback response to stressor anti-AChEs marks the initiation of progressive damage caused by the production of excess AChE. AChE, an important constituent of cholinergic neurotransmission, may thus cause neuropathological damage when it accumulates in the mammalian brain over long periods. Like many other essential proteins, AChE should be there at the right time and in the right amount or else it can initiate a vicious cycle of long-term harmful responses.

Acknowledgments

Writing this article would not have been possible without the contribution of my co-workers. Special thanks are due to Daniela Kaufer, Alon Friedman, Ella Sklan, and Noa Farchi for research contributions and to Eyal Soreq for artwork. Socioeconomic Gradient in Health

Model

Explanations

Glossary

<i>Psychosocial factors</i>	Measurements of psychological phenomena that relate to specific social environments.
<i>Social exclusion</i>	People or areas that suffer from a combination of linked problems such as poor health, unemployment, inadequate skills, low incomes, poor housing, high crime rates, lack of educational opportunities, and family breakdown.
<i>Socioeconomic gradient</i>	The positive association between greater socioeconomic disadvantage and the amount of death, disability, and disease.
<i>Socioeconomic status</i>	An individual's rank or status in a social hierarchy, usually evaluated with reference to a person's access to and consumption of goods, services, and knowledge in a society.

Socioeconomic Gradient in Health

The association between health and socioeconomic status results in the socioeconomic gradient in health. In rich countries, people who are more socioeconomically disadvantaged have poorer health and higher

levels of chronic and infectious diseases. In poor countries, there is a similar socioeconomic gradient in infectious diseases and an emerging socioeconomic gradient in chronic diseases such as obesity.

These observed socioeconomic gradients are not simply a question of poverty. [Figure 1](#) shows the infant mortality rate by levels of wealth in some of the poorest countries in the world. There is a strong socioeconomic gradient in infant mortality, with richer people, in the poorest countries of the world, having much lower rates of infant mortality compared to poorer people. It is not just the poor who have high infant mortality rates. Those who are not poor, but also not rich, have higher infant mortality rates compared to the richest groups in poor countries.

Furthermore, within rich countries, there is a socioeconomic gradient in health even among relatively well-off sections of society. One of the most famous examples of this comes from the Whitehall and Whitehall II studies of British civil servants. In the original Whitehall study, which started in 1960, the initial finding after 5 years of follow-up was that coronary heart disease mortality was higher in the lower employment grades of the British civil service. After 25 years of follow-up, there was a similar finding of an inverse gradient in mortality: the lower the grade, the higher the mortality. Data from the more recent Whitehall II study (1985–2004) shows a similar inverse gradient in all-cause mortality. In [Figure 2](#), as we proceed lower down the civil service hierarchy of jobs, the risks of mortality increase for all-cause, cardiovascular, and coronary heart disease deaths. It is not just the poor who suffer from higher levels of mortality and disease. Those who cannot be described as being in poverty, such as clerical British civil servants, have poorer health than the people at the top of the socioeconomic hierarchy.

Figure 1 Infant mortality rates by wealth quintiles in Mali, Nigeria, Benin, Yemen and Madagascar. Data from Gwatkin et al. (2000).

Figure 2 Percentage distribution of deaths by employment grade, adjusted for age and sex: Whitehall II cohort followed up for 19 years.

Socioeconomic status (SES) refers to an individual's rank or status in a social hierarchy, usually evaluated with reference to a person's access to and consumption of goods, services, and knowledge in a society. A number of different measures have been used as proxy indicators of SES, including income, educational level, and occupational prestige. Although they all display similar socioeconomic gradients in health and disease, it is important to distinguish between different measures of SES, as they may affect health through different mechanisms and pathways. For example, education is likely to have indirect effects on health through positive effects on occupation and income as well as on other factors influencing health, including health-related behaviors such as smoking and diet.

Furthermore, measurements of SES need to specify which period of life they are meant to represent. Socioeconomic disadvantage can accumulate over a lifetime, from early childhood, to school level education, to work experiences and living conditions, and on to retirement. Each of these periods of socioeconomic disadvantage can have independent effects on health later on in life. Because being disadvantaged at an earlier period increases the risk of being disadvantaged later in life, measures of SES across the life course are usually correlated with each other. However, a measure of SES in mid-life may not adequately capture the specific risks for poor health that arise from living in disadvantaged socioeconomic circumstances in childhood.

Any explanation of the association between SES and health has to take account of the socioeconomic gradient. This is not just a question about a divide between those living in poverty and others. Explanations need to take account of the socioeconomic gradient in risk factors for disease and mortality and their distribution across the population. Furthermore, the challenge for explanations is not only to explain the socioeconomic gradient, but also to suggest how it is possible for everyone in the population to have the good health enjoyed by those at the top of the socioeconomic ranks. In order to progress toward eliminating socioeconomic gradients in health, we need to understand the causes of this gradient in health. For this, we need to have an appropriate model to describe how SES can get under our skin and affect health.

Model

It is not difficult to understand how poverty in the form of material deprivation – dirty water, poor nutrition, lack of medical care – can account for the

poorer health and higher mortality of poor people. However, poverty alone cannot explain the socioeconomic gradient in health. First, dirty water, lack of calories, and poor medical care cannot account for why British civil servants who work in clerical jobs are over twice as likely to die compared to those in the top ranks of the civil service. Furthermore, the poverty-only model fails to take into account the fact that relief of such material deprivation is not simply a technical matter of providing clean water or better medical care – those resources are socially determined. Even among poorer sections of society, those who are relatively better off are more likely to take advantage of policy interventions to provide better material living conditions, thereby potentially perpetuating and increasing the socioeconomic gradient in health.

In order to reduce inequalities in health, we need to understand the mechanisms and pathways that link the socioeconomic circumstances to health. [Figure 3](#) presents a simplified model of how different causal factors link the social structure to cardiovascular disease outcomes. This helps us to understand the different mediators and pathways linking SES to health.

Figure 3 Model of social determinants of health.

This is not meant to be a complete model but a simplified representation. There are further causal factors that may be added to the model, and more causal arrows that may be drawn. This model, in particular, draws our attention to how potential causal factors in the work, social, living, and material environments relate to health behaviors or to more direct psychological processes that influence the psycho-neuro-endocrine-immune systems of the body.

This model helps us to understand how different causal factors interrelate, and it also provides a guide to potential points of intervention for reducing inequalities in health. For example, the metabolic syndrome is a risk factor for heart disease. Treatment of the metabolic syndrome through medical care may reduce heart disease, but may not reduce the socioeconomic gradient in heart disease if poorer people are less likely to have access to or get treated for the metabolic syndrome. Another potential point of intervention could be to change the health behaviors that influence the development of the metabolic syndrome. Getting more people to quit smoking may reduce the development of the syndrome, but telling people to quit smoking alone is not enough. The model suggests that there is a socioeconomic gradient in smoking that alerts us to the socioeconomic factors that underlie smoking behaviors. In order to reduce the socioeconomic gradient in the metabolic syndrome and consequently reduce heart disease, we need to understand the causes of the causes: the living, working, social, and material environmental contexts in which these health behaviors originate and operate. So if stressful work circumstances make it hard to give up smoking, we need to identify interventions that reduce stress at work. If being poor makes it hard to afford quitting smoking aids, then these aids need to be made freely available.

Explanations

The concept of multiple causal factors operating in conjunction with each other, as outlined in [Figure 3](#), is not unique to the development of chronic diseases. Although the tubercle bacillus is the specific cause of tuberculosis, most people infected with the tubercle bacillus do not have clinical tuberculosis. Other factors, such as those associated with poverty and nutrition, influence susceptibility to the disease. In the case of tuberculosis, exposure to an infectious agent is not enough to cause a disease. The exposure, in conjunction with the socioeconomic circumstances, affects the development of the disease.

Similarly, we do not believe that the material, behavioral, psychosocial, and environmental causal

factors outlined in [Figure 3](#) operate in isolation. The division of explanations of the socioeconomic gradient in health into these categories often dismisses the interrelationships and interactions between all of them. So instead, the following sections highlight some of the broad groups of factors related to the social determinants of health, all of which encompass different dimensions and combinations of material, behavioral, psychosocial, and environmental factors.

Early Life

Research from observational and intervention studies shows that the foundations of adult health are laid in early childhood and even before birth. Slow growth, poor emotional support, and socioeconomic deprivation in childhood increase the risk of poor physical, emotional, and cognitive functioning in adulthood. There is a strong patterning of these childhood risk factors for poor adult health by SES.

A number of factors associated with pregnancy, such as nutritional deficiencies during pregnancy, maternal stress, maternal smoking, misuse of drugs and alcohol, insufficient exercise, and inadequate prenatal care, can lead to less than optimal fetal development, low birth weight, and subsequently to an increased risk of heart disease in adulthood. A mother living in poorer socioeconomic circumstances is much more likely to experience some of these risk factors for poor fetal development compared to a mother living in better circumstances.

Infancy is a particularly important period of time for the development of integrated biological systems with long-term consequences for adult health. Research shows that biological systems in infancy are highly malleable through cognitive, emotional, and sensory inputs into the brain. Insecure emotional attachment and poor stimulation in infancy can lead to problematic behaviors in childhood, and adolescence as well as low educational attainment. This in turn increases the risk of social marginalization in adulthood and the ability to obtain employment or steady jobs. Furthermore, health-promoting behaviors in adulthood, such as exercise, healthy diet, and not smoking, are influenced by such parental behaviors in childhood.

It has been argued that parental poverty starts a chain of social and biological risk. Parental poverty increases the risk of poor fetal development, stimulation, and emotional and cognitive inputs in infancy. This leads to slow growth in childhood, poor behavior and educational attainment at school, leading to a raised risk of unemployment, low-status jobs, and lower SES. All of these links in the chain have consequences for physical and mental health in adulthood.

and old age – some of them indirectly, through influencing the risks further down the chain, others more directly influencing adult health. However, it is also possible to break the links between the chains at critical periods of social and biological development. This is the area where interventions on reducing the socioeconomic gradient in health need to concentrate.

Social Exclusion

Absolute poverty, defined in terms of a lack of basic material necessities of life, continues to exist, even in the richest countries. The long-term unemployed, many ethnic minority groups, guest workers, disabled people, refugees, and homeless people are at risk of living in absolute poverty in rich countries. Homeless people living on the streets have the highest rates of premature death. In poorer countries, the proportion of people living in absolute poverty is much larger than in richer countries, and this contributes to the poorer health in these countries relative to richer countries.

However, absolute poverty alone does not explain all of the socioeconomic gradient in health. Relative poverty, often defined as living on less than 60% of the national median income, affects a greater proportion of people in a population than absolute poverty. It could deny people access to decent housing and jobs, education, transport, and other vital factors for full participation in social life.

The stresses of living in absolute and relative poverty are particularly harmful during pregnancy, to babies, and to the elderly, when people are particularly vulnerable. People move in and out of poverty during their lives, so the number of people who experience poverty and social exclusion during their lifetime is far higher than the number of socially excluded people at any one time.

Furthermore, poverty and social exclusion increase the risk of social isolation, influencing divorce and separation, disability, illness, and addiction. Social isolation affects individuals and communities. Communities and neighborhoods that experience high levels of unemployment, deprivation, poor housing, and limited access to services often have far poorer health outcomes than would be expected by aggregating the number of poor people living in those communities. Social isolation in such communities is hard to escape from, as social exclusion and social isolation are intertwined, often forming a vicious cycle.

Unemployment

Unemployed people and their families have substantially increased risks of premature death and poorer physical and mental health compared to those with

stable employment. People who are long-term unemployed, in particular, have much poorer health than the employed. The health effects of unemployment are linked to both its psychological consequences and the financial problems it brings.

The health effects start when people first feel that their jobs are threatened, even before they become unemployed and before any change in their financial circumstances. Job insecurity has been shown to increase the risk of anxiety and depression, sickness absence, smoking, lack of exercise, and heart disease. Unsatisfactory jobs can be just as harmful to health as unemployment; merely having a job will not always protect physical and mental health. As job insecurity grows, it can act as a chronic stressor whose pernicious effects on health increase with the length of exposure.

Disability and ill health increase the risk of unemployment. So the association between unemployment and health could be a result of prior ill health (or selection) or the effects of unemployment on health. There is evidence for both causal models. Any interventions aimed at reducing the association between unemployment and health need to take account of the risk of unemployment through ill health as well as the risk of ill health through unemployment.

Addiction

Alcohol dependence, illicit drug use, and cigarette smoking are all closely associated with socioeconomic disadvantage. Addictions to these substances may help alleviate some of the stressors associated with socioeconomic disadvantage, but in turn, they can generate further problems as well as have long-term consequences on biological systems.

Some of the transitional economies of Central and Eastern Europe experienced great social upheaval following the end of Communist governments at the end of the twentieth century. In these countries, deaths linked to alcohol use – such as accidents, violence, poisoning, injury, and suicide – rose sharply in the 1990s. Some have argued that this sudden increase in alcohol-related deaths was due to the changed socioeconomic circumstances in these countries. In the Whitehall II cohort, a stressful work environment, measured by an imbalance between effort and rewards at work, was found to be a risk factor for alcohol dependence in men.

Smoking is a well-established and important cause of ill health and premature death. Socioeconomic disadvantage is associated with high rates of smoking and very low rates of quitting. Furthermore, smoking is a major drain on poor people's incomes, thereby contributing to further financial deprivation as well

as increasing risks of ill health. Simply increasing the price of cigarettes, to decrease the rates of smoking, may actually increase the socioeconomic gradient in smoking. Tackling addictions requires attention to the social determinants of these addictions.

Food

A good diet and adequate food supply are central for promoting health and well-being. Shortage of food and lack of variety cause malnutrition and deficiency diseases, which in turn are causes of other infectious and chronic diseases. While food deficiency occurs in poorer countries, in richer countries, excess food intake contributes to cardiovascular diseases, diabetes, cancer, and obesity. Furthermore, food poverty can exist side by side with food abundance. Some developing countries are experiencing the double burden of obesity and malnutrition-related diseases.

Economic growth and improvements in housing and sanitation resulted in an epidemiological transition from infectious to chronic diseases, as well as a nutritional transition. Diets have changed to overconsumption of energy-dense fats and sugars, producing more obesity. In rich countries, as well as some developing poor countries, obesity is becoming more common among the poor than the rich. The main dietary difference between socioeconomic groups is the sources of nutrients. The poor tend to substitute cheaper processed foods for fresh food, with much higher levels of energy-dense fats and sugars. People on low incomes are least able to obtain key nutrients from their diets.

The important public health issue is the availability and cost of healthful, nutritious food. Telling people they should eat healthfully is of little use when they do not have access to healthful food, either because they cannot afford it or because they live in food deserts where shops sell processed foods that are inexpensive but unhealthful.

Exercise

As mechanization has reduced the exercise involved in jobs, housework, and commuting, people need to find new ways of building physical activity and exercise into their lives. Regular exercise protects against heart disease and diabetes by limiting obesity. It also promotes a sense of well-being and can protect older people from depression.

There is a strong socioeconomic gradient in leisure-time physical activity – people from lower socioeconomic positions exercise less. This may be because they have less time to spend on exercise, they do not have access to leisure sports facilities, or they live in an environment that does not encourage walking or cycling.

Social Support

Supportive relationships are important emotional and practical resources that contribute to health. Social support may buffer the effects of negative events in a person's life, helping them to cope better with the effects of unemployment or disability. Alternatively, social support may directly contribute to a person's health by making him or her feel cared for, esteemed, and valued. Belonging to a social network and having mutual obligations have a powerful protective effect on health.

Social isolation, or the absence of social networks, is associated with increased rates of premature death and poor chances of survival after a heart attack. People who get less social and emotional support from others are more likely to have depression, poorer well-being, and higher levels of disability from chronic diseases. In addition, negative aspects of support from close relationships can lead to poor mental and physical health. Poverty can contribute to social isolation and negative social support.

Social cohesion, defined as the quality of social relationships and the existence of trust, mutual obligations, and respect in communities, helps to protect people and their health. Some argue that social inequalities tend to corrode good social relations and destroy social cohesion. Societies with high levels of income inequality tend to have less social cohesion and more violent crime. The breakdown of social relations, which is linked to greater inequality, reduces trust and increases levels of violence. Declines in social cohesion in some communities have also been linked to increases in rates of heart disease.

Stress

Disadvantaged social and psychological circumstances can cause long-term stress. Continuing anxiety, insecurity, low self-esteem, social isolation, and lack of control over work and home life have powerful effects on health. Such psychosocial risks accumulate during life and increase the chances of poor mental health and premature death. People in lower socioeconomic groups are more likely to experience these psychosocial stressors.

Psychosocial and other stressors activate hormones and the nervous system by triggering the fight-or-flight response: raising the heart rate, mobilizing stored energy, diverting blood to muscles, and increasing alertness. This stress response diverts energy and resources away from many physiological processes important to long-term health maintenance. While biological stress responses to acute stressors are healthy, both the cardiovascular and immune systems may be affected if there are repeated exposures

Figure 4 Heart rate variability by employment grade. Data from Hemingway et al. (2005).

to psychosocial stressors or if it goes on for too long. In the Whitehall II cohort, men from lower civil service grades had higher heart rates and lower heart rate variability, indicating poorer autonomic function (see Figure 4). In addition, those with low job control, an indicator of stress at work, were more likely to have impaired autonomic function.

Policy

Health policy was once thought to be about the provision and funding of medical care. This is now changing. While medical care can prolong survival and improve prognosis after some serious diseases, the socioeconomic conditions that make people ill in the first place are more important for the health of the population.

A review of policies in European countries identified several that took action on the social determinants of health, including policies on taxation, old age pensions, sickness benefits, maternity or child benefits, unemployment benefits, housing policies, labor markets, and community facilities. These policies may not be directly related to health, but the evidence suggests that they form part of the broader causes that indirectly influence health. The World Health Organization has set up an independent Commission on the Social

Determinants of Health, with the mission to influence public policy, both national and global, to take into account the evidence on the social determinants of health and interventions and policies to address them.

Policies at all levels of government, and between national governments, need to take account of the evidence on the social determinants of health. Improving access to medical care is important for reducing the socioeconomic gradient in health. However, policies relating to poverty reduction, education, work stress, transport, unemployment, addiction, and social exclusion – policies that cut across the whole business of government – are also needed.

The evidence suggests that telling individuals what they should do to improve their health does not reduce socioeconomic gradients in health. Understanding the causes of the causes implies emphasizing the social determinants of these health-promoting behaviors and recommending social, political, and economic interventions leading to healthier behaviors and healthier outcomes.

Conclusions

Glossary

Health risk behavior

An action carried out by people with a frequency or intensity that increases risk of disease or injury, whether or not the person is aware of the link between the activity and risk of disease or injury.

Positive health behavior

An action that may help prevent disease, detect disease and disability at an early stage, promote and enhance health, or protect from risk of injury.

Definition of Health Behavior

There are two broad classes of health-related behaviors: risk behaviors and positive health behaviors. A health risk behavior can be defined as an activity carried out by people with a frequency or intensity that increases risk of disease or injury, whether or not the person is aware of the link between the activity and risk of disease or injury. Common health risk behaviors include smoking, drinking and driving, drug abuse, and certain sexual practices. The definition of risk behavior recognizes that “dose” is important, as some activities carry no risk in moderation but are problematic when carried out at a high level (e.g., alcohol consumption).

Positive health behaviors are activities that may help prevent disease, detect disease and disability at an early stage, promote and enhance health, and protect from risk of injury. Such behaviors are defined by medical, scientific, and social consensus and are not immutable. As knowledge evolves and the nature of environmental risks is modified, different actions may come to be defined as positive health behaviors. Typical positive health behaviors are regular physical exercise, avoidance of dietary fat, consumption of fruit and vegetables, use of sunscreen protection,

breast self-examination, regular dental care, and use of vehicle seat belts.

Importance of Links with Stress

Not all health behaviors are related to stress. Even when behaviors are linked with stress, there are typically many other influences on the frequency and intensity of the activity. Health behaviors are embedded within a complex sociocultural matrix, with factors such as tradition, legislation, taxation, income, and systems of provision all influencing lifestyle and health behavior. Thus, alcohol use is not only modified by stress, but also is related to religious and social traditions, costs relative to disposable income, family experiences and peer group influences, and individual attitudes and habits. Leisure-time physical activity can be used as a way of coping with stress, but is also affected by other motives such as interest in sport and concern about appearance and by availability of a safe place to exercise, cost, time constraints, health status, and cultural attitudes.

Nevertheless, stress does have a significant role in many health behaviors, and this can be important for understanding associations between stress and health. The reason is that if stress does increase the occurrence of a health risk behavior or decreases a positive health behavior, then these behaviors may mediate the influence of stress on health risk. Indeed, changes in behavior sometimes play a more important role in the stress–health relationship than neuroendocrine, autonomic, and immunological responses. For instance, one study evaluated the impact of work stress on the development of hypertension (high blood pressure) over a 5 year period among male air traffic controllers. Some 20% of the air traffic controllers who initially had normal blood pressure developed hypertension during the study. This might be assumed to have been the result of sustained neuroendocrine and autonomic activation elicited by working in this responsible and stressful job. However, it was found that alcohol consumption also rose in individuals who became hypertensive, and it was this factor that accounted for the increase in blood pressure. Thus, the association between work stress and cardiovascular disease was mediated by a health-related behavior rather than by activation of biological stress pathways.

Other examples can be found in the epidemiological literature on psychosocial factors and health risk. A study reported by Everson and colleagues of a large sample of middle-aged men in Finland explored associations between hostility and cardiovascular disease mortality over a 9 year period. It was found that high

levels of hostility measured at the beginning of the study predicted cardiovascular mortality independently of known risk factors such as cholesterol and socioeconomic status. However, when smoking, alcohol consumption, body mass index, and physical activity were taken into account, the association between hostility and mortality was diminished substantially. This suggests that the influence of hostility was mediated not by neuroendocrine pathways, but rather by differences in health behaviors. The more hostile individuals were also those who smoked, drank alcohol excessively, and were overweight and physically inactive, which accounted for the increase in cardiovascular risk.

Health behaviors also influence links between stress and health outcomes in patients with medical conditions. One important health behavior in many illness states is adherence to medication and health advice. Low adherence can result in ineffective treatment and risk to future health. Poor adherence is affected by life stress and by states of subjective distress and depression. This might explain why, for instance, cardiac patients who suffer depression and distress following a myocardial infarction are at increased risk for recurrent cardiac events.

Thus, the relationship between health behavior and stress is of interest not only in itself, but also for its role in mediating health effects.

Different Behavior–Stress Relationships

The association between stress and health behavior can take several forms, which complicates systematic investigation, particularly in humans. The different possibilities are outlined in [Figure 1](#). The first model ([Figure 1a](#)) shows that behavior change is one aspect of the psychobiological stress response. Just as stressful episodes elicit distress and physiological adjustments, they also stimulate changes in behavior. Stressful life events, for instance, may lead to increases in cigarette smoking or dietary fat intake, or an increased likelihood of drinking and driving, in the same way that they elicit upsetting emotions. The different elements of psychobiological stress responses are typically coupled only loosely. Hence, although changes in health behavior would be expected to correlate with an increased distress in response to stressful episodes, the association may be relatively weak.

The second possibility is that changes in health behavior are stimulated by the distress that people experience during a stressful episode in their lives ([Figure 1b](#)). For example, increased alcohol consumption may occur in response to family conflict in

Figure 1 Stress and health behaviors.

individuals who become very depressed or anxious. Under these circumstances, the changes in health behavior arise not as a direct consequence of exposure to stressors, but indirectly as a result of mood change. If a person experiencing a threatening event does not become distressed or copes well with the event, there may be no change in behavior. A threshold of distress may exist below which no alteration in behavior will be measurable.

Third, the physiological adjustments that take place as part of the stress response may provoke changes in health behavior (Figure 1c). It has been proposed, for example, that elevated glucocorticoids in response to stress modulate the control of feeding and preference for foods high in fat and sucrose, and that these serve in turn to dampen adrenocortical and sympathetic nervous system responses. This pathway may contribute to the effects of stress on long-term fat consumption and hence on cardiovascular and metabolic disease risk. When such a process operates, the behavior change will take place only secondarily and not directly as part of the stress response.

Health behaviors can, in turn, influence the magnitude of the physiological adjustments that contribute to stress responses (Figure 1d). Alcohol consumption, smoking, and diet all have effects on immune function. If changes in these behaviors take place during stressful episodes, they may modulate the extent of immunosuppression during stress. Similarly, regular physical exercise has been shown in some studies to reduce the magnitude of cardiovascular and affective reactions to stress, whereas functional foods may alter physiological adjustments by increasing the bioavailability of neurotransmitter substrates.

Figure 2 Health behavior change as a coping response.

Health Behaviors as Coping Responses

Thus far, changes in health behavior have been described as direct or indirect components of the stress response. A further possibility is that people change their health behavior in an effort to cope with distress and ameliorate their negative emotional states (Figure 2). Health behavior change may therefore not be part of the stress response, but may occur as one element of the way in which people attempt to manage stress responses. There are several familiar examples of health behavior changes as coping responses. Some people turn to comfort foods such as chocolate when upset, whereas others engage in vigorous physical exercise in order to improve their mood or distract themselves from the troubling situation. These health behaviors may be effective in managing stress. Thus, it has been found that vigorous

physical activity in smokers who are trying to quit can help ameliorate sensations of craving. But in other cases, the beneficial effects of the behavior as a coping response may be more apparent than real. For instance, a large proportion of smokers believe that smoking helps relieve tension and manage stress. However, studies indicate that smoking is associated with poor well-being rather than positive states and that giving up smoking leads to reductions in perceived stress. While smoking may aid mental concentration by increasing alertness in the short term, there is little evidence that it is an effective coping behavior in most circumstances. In Western society, alcohol is sometimes used as a palliative; people drink to cope and disengage from their troubles. Unfortunately, this palliative also has adverse effects and may ultimately become a source of stress in itself.

These different associations between health behavior and stress are not mutually exclusive. An increase in alcohol consumption may, for example, be a direct response to stress (Figure 1a), as well as being a coping behavior (Figure 2). Links between stress and health behavior are therefore not straightforward, which in turn has implications for research designs.

Study Designs in the Investigation of Health Behavior

Experimental studies in animals and humans can be used to tease out associations between stress and health behavior. They allow antecedent conditions to be controlled carefully so that the impact of defined stimuli can be explored systematically. However, because much interest is focused on mental and physical health outcomes, observational studies of naturally occurring stressors are also essential. A major problem that has limited progress in the investigation of stress and health behavior has been the use of cross-sectional designs in naturalistic studies. These prevent conclusions from being drawn about causality. For example, a study of drug dependency might show that drug-dependent individuals frequently live in deprived conditions, experience a high frequency of adverse life events such as family disruption, divorce, and job loss, and have poor social supports. There is therefore an association between stress and drug dependency, but are these adverse social conditions the effects of drug dependence or did they stimulate drug use in the first place? Without longitudinal or prospective study designs, cause and effect cannot be distinguished.

Another design problem in some studies of health behavior is sample selection. A study that focuses on individuals with problems related to a particular behavior may produce results that are not broadly

representative. Many studies of stress and alcohol use, for instance, have been carried out with samples of people suffering from alcohol-related problems. There may be other people in the population, however, who drink as much alcohol as the people in these samples without suffering from health problems. Studies of individuals with health problems will be biased toward observing stress-related effects that would not manifest with a population-based sampling frame.

Conclusions

Health risk and positive health behaviors show complex relationships with stress, as they can be both elements of the stress response and coping behaviors. A combination of research designs is needed to delineate these associations, and the inferences that can be drawn from cross-sectional studies are very limited. Health behaviors require detailed investigation in the context of stress research, as they contribute to many of the associations between stressful phenomena and health risk identified in the literature.

Introduction

Overview of Pathophysiology

Psychosocial Risk Factors for Coronary Heart Disease

Individual Coronary Heart Disease Risk Factors

Cardiac Stress Management Interventions

Conclusion

Glossary

<i>Atherosclerosis</i>	A condition in which fatty plaques build up in the coronary arteries.
<i>Cardiovascular reactivity</i>	An excessive hemodynamic response to stressors.
<i>Coronary heart disease</i>	A usually symptomatic condition in which cardiac function is impaired (thought to result from atherosclerosis).
<i>Myocardial infarction (MI)</i>	A heart attack.
<i>Myocardial ischemia</i>	The inadequate supply of blood to cardiac tissue.

Introduction

Chronic cardiovascular diseases (CVD), including coronary heart disease (CHD), high blood pressure, and stroke, is the leading cause of death in developed countries. CVD is caused by the interaction of physiological, environmental, and behavioral variables, many of which are a function of individuals' lifestyles

and can, to some extent, be controlled and modified by the individual.

Despite the decline in cardiovascular mortality, CVD continues to be the leading cause of death in the United States, and an increasing body of evidence suggests that exposure to chronic and acute psychological stress may play a role in the development and/or triggering of cardiovascular pathology. This article provides a selective overview of current knowledge regarding the role of acute and chronic stress as risk factors for coronary heart disease.

Overview of Pathophysiology

Coronary atherosclerosis, which is a precursor to symptomatic coronary heart disease, results from the formation of plaques (fatty deposits) on the arterial walls that obstruct blood flow to the heart. Myocardial ischemia results from this inadequate blood supply and is often accompanied by chest pain, also known as angina pectoris. The occurrence of frequent and severe myocardial ischemia increases the risk for cardiac-rhythm disturbances, which can result in sudden cardiac death. Prolonged or severe ischemia, or plaque rupture in the coronary arteries, which may result in complete blockage, can lead to more serious manifestations of CHD. These include death of cardiac tissue (MI), also known as a heart attack, and sudden cardiac death.

Current models of the effects of acute physical and mental stress on cardiac pathophysiology suggest that the activation of the autonomic nervous system induced by behavioral factors may increase the risk of cardiovascular events. **Figure 1** illustrates pathways through which acute mental stress is linked to myocardial ischemia and clinical coronary events such as heart attack or sudden death. These links are thought to exist in individuals with preexisting coronary artery disease or dysfunction, prior MI, or poor

Figure 1 Pathophysiological model of the actions of acute stress as a trigger of myocardial infarction and sudden death in vulnerable individuals. Via its actions on the central and autonomic nervous system in patients with coronary artery disease, stress can produce a cascade of physiological responses that may lead to myocardial ischemia, ventricular fibrillation/tachycardia (VF/VT), plaque rupture, or coronary thrombosis (MI, myocardial infarction; LV, left ventricular). Reprinted from *Cardiology Clinics*, Volume 14(2), May 1996 with permission.

cardiac function, who are therefore at higher risk for these clinical events.

Psychosocial Risk Factors for Coronary Heart Disease

Psychosocial factors that have been implicated as risk factors for developing heart disease include individuals' accessibility to social and economic resources, the work environment, and stressful life circumstances. Animal model studies in primates also suggest that conditions involving psychological stress can promote the development of atherosclerosis. Each of these factors is discussed in the following sections.

Animal Model Studies

A series of studies involving cynomolgus monkeys has been conducted to examine the effects of mental stress on coronary disease. Monkeys not only have similar coronary disease pathology to humans, but they also exhibit many of the same behavioral characteristics that have been cited as potential risk factors, such as competition, aggression, and the formation of social hierarchies. Stressful situations were created for these monkeys by rearranging their social groups periodically, known as the unstable condition. Monkeys were then labeled as either dominant or subordinate based on their behavior patterns in the groups.

In one study, more coronary atherosclerosis developed in dominant male monkeys in the unstable social condition than in their subordinate counterparts. The differences in disease progression between

dominants and subordinates in the stable social condition were less pronounced. Another study, using female monkeys, found more coronary artery disease in subordinate animals than in dominants. Reproductive function was also disrupted in many of the subordinate monkeys, which may have decreased the animals' resistance to coronary disease.

Low Social Support as a Coronary Heart Disease Risk Factor

Lack of social resources, particularly inadequate social support and social isolation, can increase the risk of CVD. Social resources can be categorized as social networks or as social support derived from those networks. Social support is defined as the instrumental, emotional, and informational aid obtained from an individual's social ties and community resources, and it exerts a mediating or moderating impact on health. A lack of supportive networks also impacts health by interfering with practical aid. Research indicates that people with access to strong social networks are at a relatively lower risk of developing CHD. Social networks also exert a beneficial impact on recovery after incidence of disease.

Industrial countries demonstrate a graded, inverse relationship between socioeconomic status (SES) and morbidity and mortality, with higher disease rates appearing in poorer populations. SES has typically been defined using standard measures, including education, income, occupation, or combinations of these three factors. Although it has been shown that the prevalence of standard CHD risk factors (e.g., high

blood pressure and smoking) diminishes with increasing SES, that does not fully explain the increase in coronary mortality attributable to low SES. Regardless of other prognostic factors, social isolation and low household incomes predict an increased risk of cardiovascular death over a 5-year period. Presumably, psychological reactions to MI may be exacerbated by diminished social and economic resources.

Occupational Stress

Karasek and Theorell attempted to define specific characteristics of stressful occupations that promote risk of coronary disease. Specifically, high job strain (defined as conditions of high demand and few opportunities to control outcomes) predicted job stress-related illnesses, especially CHD. The Karasek job demand/control hypothesis explained cardiovascular disease and mortality in studies of Swedish workers and in studies of U.S. men and women.

A study of occupational stress and CHD in women also suggests that the relationship between conditions in the workplace and cardiovascular disease, at least in part, depends on family and work demands on the individual and the amount of control the individual has over these situations. The Framingham Heart Study, a major epidemiologic study of heart disease conducted by the National Institutes of Health, examined these issues. Haynes and Feinleib analyzed data from this study to address the question of whether the increase of women working outside the home has affected their cardiovascular health adversely. An 8-year follow-up of middle-age women in the mid-1960s examined the development of CHD in this population. Women who had been employed outside the home for more than half of their adult lives were compared with housewives and with men. The results indicated that generally there was not a significantly greater risk of subsequent heart disease in working women. However, there was a greater risk of CHD development in clerical workers, working women with children, and women whose bosses were unsupportive. It is thought that the increased risk in these groups is due to low job control, high family demands, or low job satisfaction. It is interesting to note that the risk of CHD increased linearly with the number of children for working women but not for housewives.

Acute Stress as a Trigger of Cardiovascular Symptoms

Research has also focused on the role of acute stress and of emotions as triggers of coronary disease symptomatology in individuals with preexisting disease. One early study observed that 40 out of 100 sudden cardiac death patients had experienced a stressful life

event (i.e., death of a spouse) within the 24 h preceding their deaths and that loss events (e.g., death of a loved one) were more common in sudden death victims than in controls. These studies support the findings of previous research that observed increased mortality of widowers from cardiovascular events.

Research has also shown an increase in cardiovascular deaths and increased rates of MI following disasters and personal traumas. The Iraqi missile attacks on Israel during the initial days of the Gulf War have been the subject of studies that examined the effect of these attacks on fatal and nonfatal cardiac events among the population living close to Tel Aviv. The intensive care unit of a Tel Aviv medical center reported an increase in acute MI cases during the week following the missile attacks (January 17–25, 1991) compared with the week prior to the attacks and with a control period consisting of the same week a year earlier.

An increase in cardiac mortality has been attributed to acute psychological stress following earthquakes and other natural disasters. For example, during the 1994 Los Angeles earthquake, the incidence of critical-care admissions for acute MI reportedly increased (odds ratio 2.4). Unstable angina, however, did not increase in the week following the earthquake compared to the week prior to the disaster, especially for hospitals within 15 miles of the earthquake epicenter.

Psychologically stressful events have also been implicated as environmental triggers occurring prior to the onset of MI. In a study of patients with acute MI, nearly half reported one or more possible triggers, the most common of which was emotional distress. Mittleman and colleagues used a more sophisticated epidemiological methodology in which each patient's activities just prior to MI were compared to a control period defined as his or her own usual levels of activity in order to examine the most common physical and mental triggers of MI. This study of MI patients interviewed a median of 4 days after the MI revealed that 39 out of 1623 patients (2.4%) reported experiencing anger within the 2 h prior to MI onset. The relative risk of MI following an anger episode was more than twice the risk during nonanger periods.

Mental Stress as a Trigger of Ischemia

Although the most important end points for studies of cardiovascular disease are MI and sudden cardiac death, research has also focused on myocardial ischemia as an intermediate measure of the effects of stress on CHD. Studies of myocardial ischemia also have the benefit of being unconfounded by reporting biases

because ischemia often occurs without symptoms that are known to the patient.

Using a structured diary method, Barry and colleagues observed that most of the episodes of daily life ischemia occurred during moderate or low levels of physical activity (e.g., talking on the phone, speaking with a friend, or clerical work). There was a graded relationship between the likelihood of ischemia and the intensity of both mental and physical activities, suggesting that as levels of physical and mental activity become more intense, they are increasingly likely to evoke transient daily life ischemia.

Gabbay and coworkers asked 63 subjects who were undergoing ambulatory electrocardiographic monitoring to fill out a more sophisticated diary. Results showed that ischemia occurred most often during moderately intense physical and mental activities. The amount of ischemic time (5%) was approximately equal for high-intensity physical and mental activities, as compared to only 0.2% of ischemic time in low-intensity activities. In summary, ambulatory electrocardiographic monitoring studies illustrate that various physical and mental activities are associated with the occurrence of ischemia during daily life. Both physical and mental activities can act as potent triggers. Thus, it seems that many features of daily life ischemia may be due to behavioral influences, including daily life stress.

Individual Coronary Heart Disease Risk Factors

Type A Behavior

The type A behavior pattern was originally described by cardiologists Friedman and Rosenman in the 1950s as a behavior pattern characterized by agitation, hostility, rapid speech, and an extremely competitive nature. The contrasting type B behavior pattern consists of a more laid-back style and a lack of the type A characteristics mentioned previously. A structured interview was developed to measure type A behavior based on behaviors such as speech characteristics and subjects' responses to various questions.

In the 1960s and 1970s, many studies were conducted to probe the relationship between type A behavior and heart disease. Most of the studies revealed a correlation between type A behavior and coronary heart disease in both men and women, which is comparable and independent of the effects of smoking and hypertension. For example, two major studies obtained results supporting the findings that type A behavior is a risk factor for heart disease. The Western Collaborative Group Study (WCGS) followed

initially healthy men for 8.5 years. The men were given questionnaires and took part in interviews to determine their type A status at the outset of the study. Those individuals who were identified as type A were more likely to have developed heart disease over the course of the 8.5 years of the study than the type B group. The Framingham Heart Study also showed that type A behavior was a predictor of CHD among white-collar men and women who worked outside of the home.

Since the 1980s, however, most studies have not corroborated the relationship between type A behavior and heart disease. The Multiple Risk Factor Intervention Trial (MRFIT) assessed whether interventions to reduce coronary risk factors, such as high blood pressure, smoking, or high cholesterol levels, decreased the potential for coronary disease in high-risk men and women. After 7 years, the results did not show a relationship between these measures of type A behavior and the incidence of the first heart attack. Further, there were reports from research that indicated that, after a heart attack, type B patients were more likely to die than type A patients. This finding could be explained as the result of healthier type A patients being the ones who initially survived their first heart attack. Regardless, however, this result certainly presented doubts about type A behavior as a coronary risk factor.

It is unclear why these studies resulted in such inconsistent findings. Some have suggested that type A behavior may be a risk factor for younger individuals rather than for older or high-risk individuals, such as the ones tested in the MRFIT study. Still, it seems that there are certain aspects of type A behavior, particularly anger and hostility, that remain correlated with coronary disease, even in studies in which overall type A behavior was not related to CHD.

Hostility and Anger

As noted earlier, it is possible that some particular characteristics of the multifaceted type A behavior are more pertinent risk factors for CHD than others, and perhaps the type A concept as a whole does not constitute increased risk. Factors that have been shown consistently to correlate with CHD are hostility, anger, certain speech characteristics drawn from the structured interview, and not expressing anger or irritation. For example, an analysis of WCGS data showed that the strongest predictors of CHD were, in fact, the potential for hostility, vigorous speech, and reports of frequent anger or irritation. The MRFIT study, which did not show a correlation between type A behavior and coronary disease, also demonstrated a relationship between hostility and an increased risk of CHD.

The Cook and Medley hostility inventory, a scale that measures certain attitudes such as cynicism and mistrust of others, has been shown to relate hostility to the occurrence of heart disease. In one study, a 25-year follow-up of physicians who completed the MMPI while attending medical school revealed that high Cook-Medley scores predicted not only the incidence of CHD but also mortality from all causes. This relationship was independent of the individual effects of other risk factor such as smoking, age, and the presence of high blood pressure. Evidence also suggests that low hostility scores are correlated with a decrease in death rates during the 20-year follow-up of the almost 1900 participants in the Western Electric Study. Research also illustrates that hostility scores are higher in low socioeconomic groups, men, and non-whites in the United States, as well as being correlated positively with smoking prevalence. Therefore, it is possible to suggest that hostility may account for some of the socioeconomic and gender differences in death rates from cardiovascular diseases.

Depression and Exhaustion

Clinical depression, which includes symptoms such as fatigue, exhaustion, and dysphoric mood, is prevalent among patients with CHD and is associated with poor health outcomes in CHD patients. Studies have reported that nearly one in five cardiac patients can be diagnosed as clinically depressed. Depression among post-MI patients, however, goes largely untreated, despite its prevalence. In several studies, the presence of a major depressive episode in CHD patients is associated with poor psychosocial rehabilitation and increased medical morbidity.

Appels and colleagues identified a syndrome of fatigue or exhaustion called vital exhaustion, which overlaps with some of the symptoms of depression. Research indicates that vital exhaustion is predictive of the development or worsening of cardiovascular disease. Further, the predictive value of fatigue or exhaustion cannot be explained by the effects of illness on mood or energy levels. Studies are currently underway to assess whether risk of death and recurrence in post-MI patients can be lessened by treating the symptoms of depression.

Responsiveness (Reactivity) to Acute Stress

It has been known for some time that individual reactions to stress vary widely, and research suggests that physiological responses to stress may be implicated in the development of CHD and/or high blood pressure. Cardiovascular reactivity is measured by assessing changes in heart rate, blood pressure, or other cardiac measures in response to stress, as opposed to the

sole measurement of resting levels of cardiovascular function. The magnitude of these responses varies widely from one individual to another. Some people are so-called hot reactors and display large increases to the challenging task, whereas others show very little or no increase at all. For example, evidence shows that behaviors present in type A individuals are often accompanied by the same types of responses that are believed to link psychosocial stress to CHD.

It may be possible that high levels of stress reactivity is a risk factor for CHD or a marker for other stress-related risk processes. Keys and coworkers followed a group of initially healthy men for 23 years and found that the magnitude of their diastolic blood pressure reactions in a cold pressor test (immersing the hand in very cold water) was a good predictor of subsequent heart disease; in fact, it was a better predictor than many of the standard risk factors. However, a later attempt to replicate these findings was unsuccessful.

Cardiac Stress Management Interventions

Evidence suggests that psychosocial interventions, when combined with the standard medical treatments for these patients and stress management, may be one way to reduce cardiac morbidity and mortality. For example, the Recurrent Coronary Prevention Project (RCPP) assessed the effects of modifying type A characteristics, such as anger, impatience, and irritability, on the recurrence of heart attacks and CHD-related deaths. Patients were divided into three groups: a cardiology counseling treatment group, a combined cardiology counseling and type A-behavior modification group, or a no treatment control group. After 4.5 years of follow-up, the type A-behavior modification group displayed significantly lower rates of heart attack recurrence than the cardiology counseling and control groups.

The Ischemic Heart Disease Life Stress Monitoring Program assigned heart attack patients to either a treatment or a control group. The treatment group was exposed to life stress monitoring and intervention, whereas the control group received only standard medical follow-ups. The results at the 1-year follow-up showed that cardiac deaths decreased by 50% and that this lower death rate persisted for 6 months beyond the end of the study.

Ornish and colleagues conducted an intervention study on 28 patients with documented coronary artery disease. Patients were assigned to either a usual care control group or a treatment group that was given a low-fat vegetarian diet, yoga-based stress

management training, smoking cessation program, and aerobic exercise. After 1 year, the results demonstrated that the treatment group showed slightly less coronary artery blockage, whereas the controls showed a progression in disease. Further, the more compliant patients in the treatment group exhibited greater disease reduction and the least compliant patients showed less change.

Finally, Blumenthal and coworkers examined the effects of an exercise regimen and stress management on CHD. The Myocardial Ischemia Intervention Trial assigned patients to receive 4 months of stress management, 4 months exercise training, or simply their standard medical follow-up care. The patients in the stress management group showed a lower risk of cardiac events in the 38 months of follow-up than the control group. There was also a lower risk associated with the exercise training group, but this did not reach significant levels.

Conclusion

There are many physiological, environmental, and behavioral influences that affect the development of cardiovascular disease. Many of the standard CHD risk factors have behavioral components, and increasingly, evidence points to important psychosocial risk factors for CHD as well, including occupational stress, hostility, and physiological reactivity to stress. In cardiac patients, acute stress, low levels of social support, and depression also seem to have an impact on the development and progression of CHD. However, several studies suggest that stress management programs, when added to usual care medical treatments, can significantly lessen cardiac morbidity in cardiac patients. Thus, it is important to consider more than simply the physiological aspects of coronary disease when discussing treatment and prevention. Greater public awareness of the aspects of coronary disease that are under individuals' control may aid in the struggle to reduce cardiac morbidity and mortality in the United States; however, continued research is needed to examine and explain these phenomena further.

Pheochromocytoma

Tumor arising from cells of neural crest origin of the medulla of the adrenal gland.

Renin-angiotensin-aldosterone system

Participates in the regulation of the extracellular fluid volume and the long-term arterial pressure, as well as in the maintenance of Na and K blood concentrations.

Glossary

<i>Apoptosis</i>	(From the Greek words <i>apo</i> = from and <i>ptosis</i> = falling); one of the main types of programmed cell death.
<i>Atrial natriuretic peptide (ANP)</i>	Released by atrial cardiomyocytes and has a direct diuretic, natriuretic and vasodilator effect.
<i>Cardiomyocytes</i>	Striated muscle cells of the heart, deriving from cardiac myoblasts; they participate in the contraction of the heart.
<i>Catecholamines</i>	Biogenic amines produced mainly from the adrenal medulla and the postganglionic neurons of the sympathetic nervous system; they participate in the stress system, influencing heart rate, blood pressure and various metabolic parameters.
<i>Cytokines</i>	Polypeptides produced in a variety of tissues; mediators of the inflammatory and immune responses.
<i>Nitric oxide synthase (NOS)</i>	Enzyme responsible for the synthesis of nitric oxide (NO).
<i>Norepinephrine (noradrenaline)</i>	A catecholamine, released both from noradrenergic neurons of the sympathetic nervous system and from the medulla of adrenal glands.

Heart failure is the end result of declining pumping capacity of the heart; it follows some initial injury to the heart, which may be of either an acute or progressive nature. In recent years, neurohormonal mechanisms that may be involved in the progression of heart failure have been proposed. These represent compensatory physiological responses activated to assist the heart and to slow down the deterioration of its pumping function. The increased secretion of catecholamines; release of various peptides with vasodilatory effects, such as the atrial natriuretic peptides; and production of the gas hormone nitric oxide all contribute in the assistance of the heart. Several cells from within the heart, however, produce other hormones, such as endothelin, with vasoconstrictive effects, which, when present at increased levels or when administered in excess, are able to partially reproduce the syndrome of heart failure in experimental animal models. These effects are generally reversible.

Stress is classically linked to elevated adrenergic activity. In the failing heart the original increase in adrenergic activity is beneficial because it facilitates an increase in the heart rate and contractility.

However, in the progress of heart failure, further increases in circulating norepinephrine occur, which may be detrimental to the myocardium. Elevated norepinephrine concentrations are positively correlated with the severity of heart failure, with the more elevated levels linked to a worse prognosis and higher mortality. Chronically elevated catecholamines may be cardiotoxic, and heart failure associated with pheochromocytoma is a well-recognized entity. Prolonged and excessive β -adrenergic receptor stimulation may result in intracellular calcium overload, which may promote cardiomyocyte apoptosis. Therefore, the effects of increased adrenergic stimulation are paradoxical and change as the disease progresses, starting as beneficial and ending as detrimental. Slowly, the failing heart may lose its ability to respond to catecholamines.

The use of antagonists of neurohormonal factors may reverse heart failure progression to some extent; thus, the use of both β -adrenergic blockade and of angiotensin-converting enzyme inhibitors partially reverse the progression of heart failure.

Stress is also associated with the production of pro-inflammatory cytokines. Recently, an important role of pro-inflammatory cytokines in the pathophysiology and progression of heart failure has been recognized. These cytokines may be produced under the influence of stress by cardiac myocytes independently of the activation of the immune system and have direct adverse effects on the cardiovascular system. Studies have specifically shown that tumor necrosis factor (TNF)- α , interleukin (IL)-2, and IL-6 exert immediate negative inotropic effects on the heart and, thus, aggravate heart failure. Increased circulating TNF- α levels are associated with more severe degrees of heart failure. It also appears that these molecules may have adverse effects on the remodeling of the cardiac cells and left ventricular structure through effects on apoptosis, as well as on the endothelium, by influencing the transcription of the NO synthase.

This knowledge has led to clinical trials studying the effects of TNF- α blockade on the progression of heart failure; these studies, however, have not shown encouraging results. Interestingly, the blockade of nuclear factor (NF)- κ B activity, which is a ubiquitous transcription factor involved in the transcription of the pro-inflammatory cytokine genes, has also been associated with an improvement in heart failure. It has thus been suggested that NF- κ B might be a promising target for future drug development for the treatment of heart failure. The current general view is that there is an interplay among catecholamines, the renin-angiotensin system, and pro-inflammatory cytokines that is involved in the pathophysiology of

heart failure. Thus, many conventional therapeutic modalities may be acting through their effects on the pro-inflammatory cytokines. One example is that angiotensin type I receptor antagonists reduce the level of circulating inflammatory mediators in patients with heart failure.

Another interesting observation linking hormones that help the body adapt to stress with heart failure was recently published. It was shown that corticotropin releasing hormone receptor 2 (CRH-R2)- and urocortin 2-deficiencies were associated with heart failure in an animal model and that the reversal of this abnormality was associated with improvement in cardiovascular function.

Finally, it was recently suggested that certain cases of cardiovascular disease may be linked to posttraumatic stress disorder (PTSD). This is not surprising because these conditions are characterized by increased sympathetic activity and elevated concentrations of circulating cytokines such as IL-6. PTSD has, indeed, been associated with heart-rate abnormalities and increased incidence of coronary artery disease; thus, although direct links of PTSD with heart failure have not been shown, the association of this disorder with coronary artery disease points in that direction.

Forms of Heart Rate Measurement

Heart Rate Assessment in Behavioral Medicine

Heart Rate Assessment in Psychological Science

Summary

Glossary

<i>Baseline</i>	A condition to which responses are compared. This can be a resting condition with no stimulation or a condition that has all the elements of the task or stressor condition except for the critical task or stress element.
<i>Electrocardiogram</i>	A changing voltage over time collected from the chest of a person using surface electrodes. The electrocardiogram's changing voltages show atrial contraction (p wave) followed by ventricular contraction (qrs wave) and then ventricular recovery (t wave). Because of its relatively large amplitude, the qrs wave is typically used as the marker for the computation of heart rate or interbeat interval, although the heartbeat is initiated by the atrial contraction (p wave).
<i>Heart rate</i>	The number of contractions (beats) of the heart expressed per unit time, typically the number of heartbeats per minute.
<i>Interbeat interval</i>	The time, typically expressed in milliseconds, between contractions of the heart.

Phasic response

A transient change in the rate of the heart (or other index) induced by an environmental or physiological stimulus. Phasic responses are typically compared to a baseline and last for a second or more but less than a minute.

Stressor/task

Any event that poses a challenge to an individual. Conditions that threaten to induce harm or pain or frustrate achievement of positive rewards are termed stressors. Conditions that pose a requirement to mentally or physically manipulate objects are typically termed tasks; these may or may not also be stressors.

Tonic response

A sustained change in the rate of the heart (or other index) induced by an environmental or physiological condition. Tonic responses are typically compared to a baseline and last for a minute or more.

Forms of Heart Rate Measurement

Clinical

The pulse, obtained by palpitation over an artery, is the basic means of obtaining heart rate in the medical clinic. The contractions of the heart are counted based on the mechanical sensation in the thumb or finger of the observer induced by the expansion of the artery due to cardiac contraction. The experience of the pulse during stress probably arises from a similar mechanism: mechanical sensations from the viscera induced by cardiac contraction – contractions that increase in force during stress. Collection of heart rate via palpitation requires the presence of another person and physical contact. The person must accurately sense the heartbeats and time the interval over which the counts are made. Use of palpated heart rate in studies of stress has been reduced due to the

possibility of error in judgments of timing and beat occurrence as well as the likelihood that the presence of a person may alter any laboratory-induced stress. Heart rate derived by this technique is typically expressed as beats per minute.

Physiological

Heart rate in physiological studies is typically derived from measurements taken from the electrocardiogram. The number of qrs waves per unit time are counted or the time between these waves is measured. Time between waves (interbeat interval) can be translated to the rate of the heart for any pair of beats. For example, if the time between heartbeats is 1000 ms (1 s), then the corresponding heart rate would be 60 beats/min; that is, 60 of these intervals of 1000 ms would equal 60 000 ms, 60 s, or 1 min. Such detailed measurements permit the tracking of how the heart is reacting beat by beat (or second by second) to environmental and physiological stimuli.

Heart rate arises from the integration of an individual's intrinsic rate with the influences of the sympathetic and parasympathetic branch of the nervous system. The heartbeat is initiated in the sinus node of the heart, which is a patch of spontaneously active neural tissue located in the cardiac atrium. The sinus node discharge rate depends on a basic intrinsic or constitutional rate for that person as modulated by the speeding influences of sympathetic nervous system firing and the slowing influences of parasympathetic system (vagus nerve) firing upon the sinus node. Thus, a second-by-second recording of heart rate provides a second-by-second record of a balance between sympathetic and parasympathetic nervous system influences on the heart.

Psychological

The sensitivity of heart rate to nervous system activation provides the justification for its use as an index of psychological stress. Stress is typically assumed to activate the sympathetic nervous system and deactivate the parasympathetic nervous system. Direct influences of the sympathetic nervous system on the sinus node as well as indirect influences via circulating catecholamines (derived primarily from the endocrine gland, the adrenal medulla) will activate β -adrenergic receptors, resulting in a speeding of the heart rate and an increase in cardiac contractility. Both nervous and endocrine reactions are transient responses to stressors. Some individuals report being in stressful circumstances lasting a year or more; such circumstances are unlikely to be directly reflected in heightened heart rate or even adrenomedullary reactions because these are reactions that return to baseline values after a brief

period. Specific stressors arising from stressful circumstances can induce tonic reactions or phasic reactions of heart rate. Reactions to stressor lasting minutes to hours can be detected by examining tonic reactions in which the average heart rate over periods of minutes can be demonstrated to be elevated relative to a baseline period. Acute reactions to specific stressors may induce transient nervous system responses lasting seconds rather than minutes. Such phasic responses are typically assessed by comparing heart rate (or interbeat interval) for the seconds after the stressor to that of the seconds just before the stressor. The rapidity with which heart rate returns to baseline can also be informative. Increased vagal activation or decreased sympathetic activation will return heart rate to baseline values. Psychological factors, such as rumination over the stressful incident, may prolong heart rate speeding in some individuals. Concurrently, physiological factors may play a role in the recovery of heart rate, e.g., some individuals may have rapid vagal activation after a stressor with consequently brief heart rate reactions to stress. In short, the measurement of heart rate as an index of stress must be gauged to the type of stress, most particularly its temporal duration.

Heart Rate Assessment in Behavioral Medicine

Cardiovascular Reactivity

Because of its influence on the cardiovascular system, stress may influence the course of cardiovascular disease. A general hypothesis, the reactivity hypothesis, states that the cardiovascular reactivity resulting from repeated stressful events might contribute to the development of hypertension, myocardial infarction, and stroke. Presumably certain individuals are predisposed to show consistent and large cardiovascular reactions to stress, or are placed in an environment in which stressors are frequent and repetitive, or both. This hypothesis has been widely investigated using both laboratory challenges to assess reactivity and the ambulatory monitoring of heart rate and blood pressure as individuals perform their usual activities. The consistency within an individual over time of heart rate responses to laboratory stress has been established. Heart rate also changes in response to daily events in ambulatory recordings.

The number and size of heart rate responses do not seem, however, to predict cardiovascular disease onset and course; blood pressure increases in response to stressors have proven more predictive. The extensive parasympathetic influence on heart rate may explain this difference in the predictive utility of heart rate and blood pressure.

Heart Rate Variability

Derived measures of heart rate related to nervous system function have been found to correlate positively with cardiovascular health. Parasympathetic influences on heart rate are exerted via the vagus nerve, which innervates the heart (along with innervation by the cardiac sympathetic nerves). The vagus is more important than the sympathetic nerves for most transient changes in heart rate. Vagal firing influencing the heart waxes and wanes with respiration; this results in heart rate increasing during inspiration and decreasing during expiration. The rhythmic changes in heart rate over time, heart rate variability, can then be used to measure vagal influence on the heart. Heart rate has been found to show rhythmic changes with lower frequencies than respiration as well. For example, a frequency of 0.1 Hz has been related in part to sympathetic activity related to blood pressure, and heart rate shows a 24-h rhythm related to the sleep–wake cycle. Variability at the respiratory rate has been shown to be due almost completely to vagal/parasympathetic activity. Variability at other frequencies is not as well defined. Relatively greater variability has in general, however, been associated with cardiovascular health. A related measure positively associated with cardiovascular health is baroreceptor sensitivity. The baroreceptors are sense organs in major arteries that sense pressure change and transmit this to the brain, which then alters sympathetic and parasympathetic control to return blood pressure to normal. Pressure increases induce a vagal activation reducing heart rate. Greater heart rate change per unit of heart rate change (baroreceptor sensitivity) is correlated with better cardiovascular health. The associations of cardiac variability and baroreceptor sensitivity with cardiovascular health have led to the hypothesis that cardiac variability, most specifically parasympathetically induced variability, may act to buffer the influence of stress on the cardiovascular system.

Heart Rate Assessment in Psychological Science

Motivation/Affect

A psychological analysis of stress typically suggests that the threat or stressor induces an affective reaction as well as influences a person's motivational state. Subsequently, coping with the stressor may require other psychological processes. Behavioral medicine investigations have not typically attempted to separate the different processes influenced by stress, but the psychological analysis raises the question of whether heart rate reactions are controlled by one or

more of the different psychological processes. The inference of a psychological process that is not directly observable is difficult, and this difficulty is compounded when the processes are as complex and conceptually overlapping as categories of affect and motivation. Studies do show that heart rate increases with the induction of most emotions, with the exception of disgust. Similarly, cues for reward or punishment can induce heart rate increases, perhaps with stronger increases related to cues for reward. Interpretation is further complicated by the possibility that coping with the affect or acting upon the motivational cue may elicit other processes controlling heart rate. For example, the induction of affect with an imaged scenario that contains an action element appears to induce greater heart rate change than induction with a more passive scenario.

Attention/Cognition

Coping refers to a set of action and mental processes that permit the person to redefine the threat and/or develop a means of neutralizing the threat. Thus, a multitude of cognitions and actions may be elicited as coping. If heart rate responds to processes such as attention and memory processes, then the involvement of these processes in coping, or even in the initial evaluation of the stressor, may be the source of phasic heart rate changes after a stressor. Muscle activation is a strong metabolic stimulus that induces rapid increases in heart rate. Similarly, change in breathing patterns, e.g., breath holding, have rapid, large effects on heart rate. These changes can readily be demonstrated in the absence of a stressor, while it is difficult to ensure that reactions to a stressor do not include muscle tension changes or changes in breathing pattern. Of greater psychological interest is attentive waiting, which induces clear phasic changes in heart rate. Heart rate decreases during the anticipation of any significant task or task element. Conceptually, heart rate seems to decrease whenever an action must be chosen at a specific point in time and potentially competing actions must be inhibited. The heart slows reliably prior to a signal to respond, even when that signal is accompanied by an electrical shock. This slowing of the heart rate does not appear to be due to respiratory changes or the inhibition of the peripheral musculature. The relevance of this observation to behavioral medicine studies of reactivity is clear. Many studies have used as their stressor/challenge computer games with periods of anticipatory attention.

Interpretive Issues

Heart rate can serve as an index of stress, but its utility and validity can be increased by a few simple

precautions. First, stress and stress reactions should be conceptualized. Should heart rate in response to an increase in muscle tension be considered a stress reaction or a muscle artifact? Second, the stressor and overall conditions of eliciting the stress reaction should be controlled or assessed so it is possible to separate heart rate changes due to motor activity, respiration, transient attention, and affect/motivation. If a tonic response is of greatest interest, than scoring of the heart rate should occur after transient changes related to attention, breath holding, and muscle tensing. Fortunately, many of these phasic changes disappear after the initial few seconds of a task or stimulus presentation. Care must be taken in interpretation to recognize all the possible sources – other than those defined as stress – of the observed change in heart rate.

Summary

Heart rate increases rapidly during stress. The response may be initiated by motivational threat, affect, or the thoughts and actions induced by the stressor. Separation of the cause of the heart rate change is difficult in both the laboratory and real life. The degree of heart rate increase in response to stress or psychological challenge has been less predictive of medically significant cardiovascular disease than degree of change of blood pressure. The degree of variability of heart rate over time has, however, been associated with relatively better cardiovascular health.

Glossary

Biofilm

A flat multicellular structure, one or very few cells thick, that consists of a single or several (consortium) species. The single-species variety appears during the normal life cycle of an organism or in response to stress. Most biofilms must adhere to a surface as a support for growth and are, like granules, more heat-resistant than are their individual components living outside the structure. Other biofilms, such as the lamina formed by the archaeon *Methanoarcina mazei* S-6, do not need to adhere to a surface for growth.

Granule

A multicellular structure or consortium composed of two or more species of organisms; it is more resistant to stressors such as heat than are the free organisms outside it.

Heat resistance

The capacity to withstand temperatures higher than 37°C without a significant loss of function; also called thermotolerance. More specifically, a cell condition characterized by an increase in the capacity to withstand temperatures above the optimal for that cell's growth, whether 37°C, higher, or lower. The cell condition involves an active process with a differential regulation of gene expression and protein levels induced by the elevation of temperature above the optimal one (heat shock); also called acquired or induced heat resistance.

Hyper-thermophile Packet

An organism with an optimal temperature for growth of 80°C or higher.

A globular multicellular structure, composed of only one species, formed by certain microbes (e.g., the archaeon *Methanosarcina mazei* S-6) as part of their life cycles or in response to environmental stressors. The packet is more resistant to stressors, including heat shock, than are the individual cells living outside it.

Thermophile

An organism with an optimal temperature for growth of 50–70°C; it prefers temperatures higher than 37°C and has constitutive heat resistance, namely an inborn capacity to carry out all of its physiological functions at temperatures that are not optimal for (or will damage or kill) human cells.

Thermo-protectant

A nonprotein molecule that plays an active role in thermotolerance by protecting proteins, and perhaps other cellular components, from the damaging effects of elevated temperatures, whether during normal growth (thermophiles and hyperthermophiles) or on a sudden increase above the optimal temperature (heat shock). There are several thermo-protectants that have rather simple structures. They are different from molecular chaperones and chaperonins, which are proteins.

Diversity of Life Forms and Habitats

In nature, living cells and organisms are diverse, encompassing a wide range of species that thrive under very varied conditions. Temperature is one of the major conditions that significantly influence the life of cells. As a reference point, bear in mind that the normal body temperature of adult humans is 36.8 (±0.4)°C and that human cells grow well in laboratory cultures at 37°C. There are, however, very many organisms, both single- and multicelled, on our planet that have optimal temperatures for growth (OTGs) that differ from 37°C, either lower or higher and sometimes radically.

Organisms are classified, according to their OTGs, into the following groups: psychrophiles (OTG 15°C or lower), mesophiles (OTG 35–40°C), thermophiles (OTG 50–70°C), and hyperthermophiles (OTG 80°C or higher). Within the mesophiles, those that can still grow at 0–4°C are termed psychrotolerant; within the

hyperthermophiles, those that have OTGs above 95°C are termed extreme thermophiles.

Although organisms grow best at their OTGs, they can also grow and multiply, albeit more slowly, within temperature ranges on either side of their optimum. For example, the mesophilic organism *Methanosarcina mazei* S-6 displays its fastest growth rate at 37–40°C, but it is capable of growing and multiplying within the 25–45°C range. Likewise, the extreme thermophile *Pyrolobus fumarii* has an OTG of 106°C, but it can grow at temperatures between 90 and 113°C. Determinations of this sort have shown that the maximum temperature at which any given organism can grow is closer to its OTG than to the minimum that still allows its survival. This suggests that, as a general rule, organisms are more sensitive to overheating than to cooling. Excess heat may kill (lethal temperature), whereas a comparable excess of cold may only slow down the functions of the cell.

Cells exposed to an elevation of temperature above their OTGs are stressed, or heat shocked, and they mount a stress or heat shock response. This response is characterized by the activation of stress (heat shock) genes along with the slowing down or shutting off of many other genes. The stress genes produce stress (heat shock) proteins, some of which are molecular chaperones; the latter play a role in cell survival during stress and recovery after stress.

Definition

Heat resistance, also called thermotolerance, is a condition that makes the cell capable of withstanding a temperature excess. Because of this capability, the cell can survive a heat shock that would otherwise be lethal.

If we use as a reference point the OTG for human cells, 37°C, we can recognize two main types of thermotolerance: constitutive and acquired. The former pertains to organisms that normally grow at temperatures considered stressful or lethal for human cells, as exemplified by the thermophiles and hyperthermophiles.

Acquired thermotolerance, in contrast, is an experiential tolerance that an organism gains after a heat shock. The following experiment illustrates a typical case of acquired thermotolerance. Cells from a hyperthermophilic organism with an OTG of 80°C, but that can grow within the 60–86°C range, was heat-shocked when exposed to 88°C (sublethal temperature for this organism) for 1 h, but it was killed by exposure to 92°C (lethal temperature). Remarkably, cells that had been heat shocked at 88°C did not die when they were subsequently exposed to the lethal temperature. The heat-shocked cells had acquired

thermotolerance; the cells were able to survive a lethal temperature because they had been prepared (preconditioned) by preexposure to a sublethal, heat-shocking temperature.

Cross-Tolerance

Temperature excess is a cell stressor, but it is not the only one known. There are many cell stressors of mechanical (e.g., compression and shearing), physical (e.g., heat and ultraviolet radiation), or chemical (e.g., alcohol, hydrogen peroxide, high salinity, and lack of oxygen) nature that elicit a stress (heat shock) response in cells. Interestingly, stress tolerance induced by one stressor may also result in efficient resistance (i.e., cross-tolerance) to other stressors. Thus, thermotolerance induced by heat shock may also increase the resistance to a chemical stressor and vice versa. Cross-tolerance to stressors is of extraordinary potential value to fields such as medicine and surgery.

Mechanism

Heat resistance or thermotolerance is mediated by a variety of factors and mechanisms: stress proteins, molecular chaperones, chaperonins, thermoprotective compounds, innate characteristics of proteins that make them thermostable, cell-wall composition and architecture, formation of multicellular structures, and formation of spores.

One of the key harmful events in heat stress is protein denaturation. If the stress is too drastic (a heat-shocking temperature far above the OTG or very prolonged heat shock), the cellular proteins denature and aggregate. Cell death ensues. An illustrative example is the hard-boiled egg. There is no known way to restore a hard-boiled egg to a viable form so that the denatured, aggregated proteins disaggregate and regain their functional, native conformation. There are, however, many instances in which protein denaturation does not reach such extreme, irreversible levels. Milder stresses cause only partial denaturation, and the damage is reversible; the proteins can be restored to their functional form. The recovery is mediated by several mechanisms, one of which involves the molecular chaperones. These chaperones are also involved in preventing protein damage and in eliminating protein molecules damaged beyond repair.

Thermotolerance is based on various mechanisms and a key one is the presence and use of all the cellular molecules and mechanisms that prevent and cure protein denaturation and also those that eliminate irreversibly damaged and aggregated proteins before these reach levels that will clog the intracellular machinery.

Chaperones and Chaperonins

Chaperones and chaperonins belong to the large group of stress (heat shock) proteins, although not all of them are the product of stress-inducible genes. Their functions are to assist nascent polypeptides in folding correctly so that each can reach a functional configuration (its native conformation), to protect the polypeptides from aggregation during synthesis and during stress, and to refold them after partial unfolding (reversible denaturation) caused by stressors such as heat.

Thermoprotectants

Thermoprotectants are simple cellular components that confer resistance to other molecules, by mechanisms not yet fully elucidated. They are considered integral to thermotolerance because they have been found in hyperthermophilic organisms and because laboratory tests *in vitro* have indicated that they stabilize protein molecules, rendering them heat resistant.

Two thermoprotectants have been studied in some detail: di-*myo*-inositol phosphate (DIP), and cyclic diphosphoglycerate (cDPG). These molecules are believed to be important for the physiology of organisms living in high-temperature ecosystems (e.g., hot springs, hot pools and mud pots, solfataras and geysers, and hydrothermal vents at the bottom of the ocean) and for their survival when stressed by the variations in temperature, pH, and hydrostatic pressure that are characteristic of these extreme environments. Trehalose, a disaccharide, has also been implicated in the mechanism of heat resistance, either alone or in association with chaperones.

Intrinsic Molecular Features

Many proteins, including enzymes, of thermophilic and hyperthermophilic organisms withstand heat stress better than do their counterparts from mesophiles, even in the absence of thermoprotectants. They are believed to have built-in structural features that make them thermostable, but the nature of these features has not been determined. It has been proposed that innumerable subtle interactions occur among various points of the molecule that confer great stability, even in the face of stressors, and enhanced resistance to the denaturation induced by the latter. The identification and measurement of these interactions have proven elusive up to the present time.

Cell Envelopes and Multicellular Structures

Many organisms, particularly those living in extreme environments, are protected from harsh environmental factors by specialized cell envelopes that are resistant to the stressors (e.g., high temperature or salinity) that are inherent to their ecosystems. In addition, many species form multicellular structures that are more resistant to stressors than are single cells. In these structures, cells are held together either by an intercellular connective material, consisting of a flat sheet with a thickness of one or very few cells or in a globular conglomerate resembling a sphere (Figure 1). The former, flat structure is called a biofilm, and it is usually, but not always, attached to a supporting surface (e.g., rock in natural habitats or sand particles in methanogenic bioreactors).

The globular structures are of two types; they are formed either by a single species or by an association of two or more species. The multispecies type is called a granule, and it constitutes a microbial consortium that can live in both natural and manufactured ecosystems. Examples of manufactured ecosystems are the anaerobic methanogenic bioreactors used in waste-processing plants. In the granular consortium, various species of microorganisms cooperate with one another in a food web that bioconverts organic molecules while being shielded from the shearing and other stressors typical of bioreactors, such as temperature and pH variations. Indeed, the consortium is very resistant to these stressors, and it survives stresses that would kill its microbial components outside the granule.

The single-species type of globular multicellular structure is formed by a single species of organism as part of its life cycle or in response to stressors. An example of a single-species multicellular structure is that built by the methanogenic microorganism *Methanosarcina mazei* S-6 in culture and in bioreactors (Figure 1). The globular morphotype, termed a packet, is considerably more resistant to mechanical, chemical, and thermal stressors than is the single-celled form of this archaeon.

Spores

Some microbes subjected to harsh environmental conditions, such as scarcity of nutrients, desiccation, and exposure to toxic substances, undergo sporulation. They form a very stress-resistant structure called a spore or endospore. The microbe becomes dehydrated, and its genetic material is enclosed in a thick coat with a special composition that is, most likely,

Figure 1 Archaeal microbe *Methanosarcina mazei* S-6. (a) Cells growing in a packet, a globular, heat-resistant multicellular structure; (b) cells growing individually. The packet is composed of many cells joined together by an intercellular connective material that also enwraps the whole structure. From A. J. L. Macario and E. Conway de Macario (2001), *Frontiers in Bioscience* **6**, d262–d283, [online].

responsible for the extreme resistance of spores to stressors, including heat.

Because spores are produced by microbes that can cause disease in humans and animals (e.g., *Clostridium tetani* and *C. botulinum*), they are of special interest to the field of medicine and to the food industry, which must resort to sterilization and pasteurization (both involving heating) to prevent contamination and infection.

Applications

Stress resistance is a desirable attribute from the organism's perspective because confrontation with stressors, such as heat shock, is a frequent occurrence in the life of any cell or organism. However, as pointed out in the previous section, microbial stress resistance may be undesirable from the human perspective, when the organisms is pathogenic and must be destroyed.

In other circumstances, when stress resistance is a convenient attribute from the medical or industrial perspective, attempts at making certain cell types more resistant to stressors are not only justified but also are an attractive scientific and biotechnologic endeavor. Means are being developed at the present time to enhance cell survival during stress and to accelerate cell recovery after stress. Briefly, the idea is to provide a cell with those elements now known to

play (or that are suspected of playing) a key role in maintaining its normal array of proteins in working condition. These elements can help in restoring the functional conformation of damaged proteins or in degrading those damaged beyond repair during and after stress. Genetic engineering and preconditioning are two approaches to achieving this; they can be applied independently of one another or in combination. Essentially, in the genetic engineering approach, an extra set of genes encoding the proteins of interest (e.g., molecular chaperones or proteases) are grafted into the genome of the target cell whose stress resistance is to be increased. Alternatively, the extra set of genes is incorporated into the cytoplasm of the cell via a self-replicating extrachromosomal element such as a plasmid. In both instances, the expression of the foreign genes increases the levels of the stress proteins inside the cell, which in turn enhances the folding of newly formed, much needed polypeptides and also the refolding of partially denatured molecules. Of course, it is a possibility that secondary effects may also occur that are negative from the standpoint of the cell, tissue, or organism we are trying to protect from the consequences of stress. Because of this possibility, many tests with experimental models are necessary to certify the benefits of this type of anti-stress treatment before it is applied to valuable cells in bioreactors or to humans in a therapeutic context.

The preconditioning approach involves the use of mild stressors, for example, chemical compounds known to induce stress genes, to generate cross-tolerance to potent stressors or the use of a potent stressor at low doses to induce a stress response of low intensity. Both procedures confer a sort of cellular memory. When the cell is challenged with a potentially very damaging or lethal stressor against which a cross-tolerance was previously induced, the cell has increased chances of survival. Likewise, a cell preconditioned with low doses of a potent stressor also has increased chances of survival when challenged with the same stressor at doses that would be lethal for a nonpreconditioned cell.

These strategies and procedures are being applied and have a promising future in the biotechnology industry and in medicine and surgery. In the biotechnology field, bioreactors (also called fermentors) are used for a variety of purposes ranging from the large-scale production of useful molecules (e.g., hormones and antibiotics) to the bioconversion of wastes. However, a drawback is that the cells in bioreactors are susceptible to stressors generated by the process itself or received with the influent (e.g., wastes). Oscillations or abrupt changes in temperature, pH, and content of toxic chemicals are common events in bioconversion technology. These stressors cause frequent bioreactor malfunctions or failures because the bioprocessing cells suffer stress, malfunction, and even die. Obviously, the generation of resistant cells, capable of withstanding the stressors, will improve the efficiency and economic value of this technology.

Another obvious need for cells equipped with strong antistress mechanisms exists in surgery. Poor oxygenation, resulting in cell stress, occurs in many tissues; most important, it occurs in the brain and heart during large-scale surgical operations, particularly those necessitating blood exchange. It is, therefore, crucial to prevent brain- and heart-cell damage and to ensure the preservation of these vital tissues. To achieve this goal, a promising strategy is to induce stress tolerance. Stress proteins, specifically molecular chaperones, are being tested in experiments whose aim is to invigorate the cells. A stress protein or its gene is introduced into the tissue to confer resistance in a manner similar to that described for microbes in bioreactors that process wastes.

An alternative approach takes advantage of cross-tolerance. Heat resistance is induced in the cells of tissues targeted for protection from ischemia hypoxia (e.g., brain and heart tissues) by mild heat shock. This preparatory mild stress, or preconditioning, is relatively harmless, yet it is sufficient to elicit a heat shock response and heat resistance, which are efficient in

counteracting the harmful effects of ischemia hypoxia during a surgical procedure.

Last, replacement therapy, genetic or otherwise, may be indicated in chaperonopathies – diseases in which deficient chaperones are the primary etiology of or significant contributors to the pathogenesis. In these instances, chaperone genes may be used in genetic engineering approaches, as described earlier, or purified molecular chaperones may be administered directly, as antibodies are sometimes provided to treat infections.

On the negative side, microbial heat resistance is an obstacle to the sterilization of surgical and laboratory instruments, plasticware and glassware, sera, solutions, culture media, and any other object or substance that must be freed from pathogenic organisms while avoiding a significant loss of biological or medicinal properties. The heat resistance of microbes also presents a problem for the food industry whenever it is necessary to improve the safety and preservation of edible products. Some very serious food-borne pathogens, such as *Clostridium botulinum*, form spores and can be in a dormant state for years until favorable environmental conditions induce their return to a vegetative, pathogenic status. The food industry must apply heat and other means to get rid of the pathogens, but only to the extent that the nutritional and sensory qualities of the product are not impaired significantly. The achievement of such a balance between killing or disarming the pathogens and preserving food quality is a major challenge for science and technology.

Glossary

<i>Endoplasmic reticulum (ER)</i>	A eukaryotic cell component consisting of a labyrinthine system of flat cavities delimited by a membrane that is continuous with the outer membrane bounding the nucleus. The ER is involved in the synthesis and transport of proteins and other molecules.
<i>Genome</i>	The complete set of genetic information carried by a cell (or organism), representing its entire hereditary complement.
<i>Genomics</i>	The cataloguing and large-scale investigation of the sequence, structure, and function of whole genomes, or of whole sets of genes and their interactions and expression patterns.
<i>Mitochondrion</i>	A eukaryotic cell organelle, evolutionarily related to gram-negative bacteria; it houses the cellular respiration apparatus and produces energy.
<i>Molecular phylogeny</i>	The science of classifying organisms through comparisons of molecular sequences. This type of classification reflects the evolution of individual molecules and shows evolutionary relationships between molecules and organisms.
<i>Nucleolus</i>	A relatively small region within the nucleus that contains the ribosomal RNA (rRNA) genes; this is where rRNA synthesis occurs.
<i>Nucleus</i>	The distinctive organelle of the eukaryotic cell (it is not present in prokaryotes), consisting mainly of packed genetic material (DNA) encased in a double membrane. Gene expression begins in

Proteomics

this organelle with transcription, which generates the messenger RNA (mRNA). The cataloguing and study of the full set of proteins encoded by a genome; also, the analysis of the set of proteins produced by a genome or a large group of genes (expression profile) under various circumstances, e.g., conditions of cell stress vs. basal conditions (no stress).

Introduction

Heat shock genes are also called stress genes. The latter is a more appropriate name, since these genes are induced not only by heat shock but also by other stressors. Hence, the term stress genes is given preference in this article.

A better understanding of human stress genes can be gained by examining them from the evolutionary standpoint rather than by studying them in isolation, without connection with the same genes in other species or with their evolutionary history. Modern molecular phylogeny has provided the means to look at genes and their proteins while taking into consideration their structural and evolutionary relations, at a level of resolution that was not attainable in the past. Furthermore, genome sequencing has now become a reality, expanding the possibilities for gene analysis and comparison beyond previously imaginable limits.

Molecular Phylogeny

Molecular phylogeny is a relatively new scientific discipline that involves the comparative analysis of the nucleotide sequences of genes and the amino acid sequences and structural features of proteins from which evolutionary histories and relationships, and in some cases also functions, can be inferred.

The basic classification of organisms furnished by molecular phylogeny is based upon the comparison of 16S/18S (small subunit) ribosomal RNA (rRNA) sequences. Thus, all living cells are divided into three main evolutionary branches or phylogenetic lines of descent termed domains: bacteria (eubacteria), archaea (archaeobacteria), and eucarya (eukaryotes).

In addition to the small ribosomal subunit rRNA, other molecules such as stress (heat shock) proteins have been used for phylogenetic analyses. One of the most convenient targets for these analyses is the stress protein Hsp70(DnaK), for the following reasons. (1) It is long enough (about 600 amino acids on average,

of which nearly 500 are conserved) to permit the occurrence of mutations at an observable level; (2) it is highly conserved, being present in virtually all organisms and cells with few exceptions, with an amino acid sequence that is very similar in all organisms; (3) it has segments that are more highly conserved than others, which allows for reliable alignments for comparative analyses of matching structural domains; and (4) it has distinctive structural features called motifs or signatures, some of which have a known function, that facilitate comparisons among molecules from different organisms, including functional comparisons without actually performing functional assays in the laboratory.

Origins of the Human Cell

Comparative analyses of sequences and sequence signatures have provided information on the evolution of organisms and consequently of their relationships (what or who is derived from what or whom). These analyses have also clarified the origins of the eukaryotic cell (including the human cell) as a whole, and those of its components.

With the preceding in mind, we can now add that a better understanding of human stress genes also requires familiarity with the components of the eukaryotic cell and their origins, as revealed by molecular phylogenetic analyses and studies of full genome sequences.

Microanatomic Components of the Human Cell

Human cells are composed of the cytoplasmic membrane that encloses the cytoplasm or cytosol in which the organelles reside. Examples of the latter are the nucleus with the nucleolus, mitochondria, Golgi apparatus, and endoplasmic reticulum (ER). Plant cells also have these various organelles, and in addition they have chloroplasts, in which photosynthesis takes place. Stress proteins are present in all the cellular compartments, whereas the genes that code for them are in the DNA of the nucleus.

Molecular phylogenetic analyses of nucleotide and amino acid sequences of various types of molecules, including stress genes and proteins, have revealed that the genes in the nuclear DNA are a mixed assemblage of bacterial and archaeal components side by side with typically eukaryotic constituents. Furthermore, it has been shown that mitochondria are derived from ancestors of modern gram-negative bacteria and that chloroplasts are descendants of the ancestors of today's cyanobacteria.

It has been concluded that the human cell is an assemblage of bacterial, archaeal, and eukaryotic

components that coexist in a functional unit. This is the result of billions of years of genetic changes, exchanges, gains, and losses during evolution from the most primitive ancestral forms to today's *Homo sapiens*.

Stress Proteins in the Various Compartments of the Human Cell

A sample of stress proteins that have been studied in human cells and whose corresponding genes have been identified and characterized, at least partially, is given in [Table 1](#), which classifies stress proteins based on molecular mass.

Comparative sequence analyses of the type mentioned in the previous sections have provided insights into the evolutionary origins of the stress proteins residing in the cytosol, nucleus, mitochondria, and ER. For instance, mitochondrial Hsp60 is derived from ancestors of modern gram-negative bacteria (it is equivalent to the GroEL chaperonin of extant bacteria), whereas the cytosolic Hsp60 is the homolog of the chaperonin subunits that compose the thermosome in modern archaea. The Hsp70(DnaK) in all compartments of the human cell is related to a gram-negative bacterial ancestor and is similar to the homologs of extant gram-negative bacteria but distinct from those of modern gram positives.

Stress Genes

Human stress genes and their proteins have been studied only to a limited extent compared to those from other eukaryotic organisms. A sample of the human cell types, cell lines, and tissues in which expression of the stress genes has been assessed is displayed in [Table 2](#).

In general, constitutive (basal) gene expression was measured and compared with expression induced by a stressor, for instance, a temperature higher than optimal for cell growth (heat shock) or some other agent of medical significance, such as a heavy metal. Whenever possible, the levels of expression in pathological cells were compared with those in normal counterparts. Overall, the results showed alterations in the levels of expression in cells from diseased tissues, increases more often than decreases, as compared with normal controls. However, the physiopathological or pathogenic significance of these alterations could not be established with certainty in most instances. This deficiency is chiefly attributable to the difficulties in designing properly controlled experiments, including direct manipulation of cells or tissues, when performing research involving human subjects and clinical samples. Hence, many more data are available from experiments done with simple

Table 1 Examples of human stress (heat shock) and molecular chaperone proteins whose genes have been at least partially identified and characterized

Family		Locale of residence in the cell ^a		
Name(s)	Mass (kDa)	Cytosol/Nucleus	Mitochondria	Endoplasmic reticulum (ER)

organisms (e.g., the bacterium *Escherichia coli*, the archaeon *Methanosarcina mazei*, and the unicellular fungus *Saccharomyces cerevisiae*) and animal models (e.g., mice, rats, and gerbils) than are available from research carried out directly in human cells or tissues.

In animal models, it has been shown, for example, that the levels of stress proteins, especially Hsp70 (DnaK), are elevated in tissues damaged by ischemia-hypoxia. Research has focused on determining the presence of Hsp70 (DnaK) in brain and heart tissues afflicted by ischemia-hypoxia. Around the dead, central zone of an infarct in the brain (stroke) or in the heart (cardiac attack), caused by occlusion of an artery and blood flow interruption, there are zones in which the brain or heart cells are not dead, but only injured. These zones are called penumbra in the brain and areas of stunned myocytes in the heart. Cells in such zones are damaged mainly due to protein denaturation. The latter may be reversible, particularly with the help of stress proteins that, like Hsp70 (DnaK), are molecular chaperones.

The Human Genome

The human genome has been sequenced, and the information is now being processed, with the data available at various websites (Table 3). It will take considerable effort over the coming years to process all the data and to complete the annotation, based on thorough analyses of each gene (genomics) and gene product (proteomics). A hint at the enormous complexity of the situation is provided, for instance, by the fact that at present there are more than 30 candidate genes that encode Hsp40 (DnaJ)-related proteins and more than 20 that encode Hsp70 (DnaK)-related

proteins. A similar situation holds true for all the other heat shock proteins and molecular chaperones.

Perspectives

A full view of the human species' stress gene candidates should become available when the sequence of the human genome has been more fully analyzed. In addition to identification of the genes through comparisons of their sequences – and those of the proteins encoded in them – with homologs of known functions from other organisms, experiments will be required to establish whether these genes are transcribed and translated and also to determine these genes' responses to various stressors. Based on the results, it should become possible to devise strategies for using the genes, their regulatory components and factors, and the proteins that they produce to both prevent and treat stress-induced lesions and diseases.

Also, a detailed phylogenetic analysis of each heat shock protein and molecular chaperone will be necessary if we are to understand their evolution and if we are to gain insight into their biological roles in organisms from the three phylogenetic domains. These analyses will also provide valuable information on the evolution and function of each protein's structural-functional domain and motif present in human heat shock proteins and molecular chaperones. In turn, this information will be instrumental for elucidating the nature of genes and gene products that are abnormal in genetic and acquired chaperonopathies; currently, only preliminary information is available for these disorders, suggesting that the affected molecules are chaperones.

Members of the HSP60 Family

Response to Heat Shock and Related Stress

Function in Protein Folding

Medical Aspects

Glossary

Chaperonin
containing
TCP-1 (CCT)

The HSP60 family member protein distributed in the eukaryotic cytosol and nucleus. CCT is also called TRiC or c-cpn.

Chaperonins

Alternative name for the HSP60 family, preferentially used by molecular biologists and biochemists. This term is often

	confused with chaperones, which refers to all molecular chaperones. The term chaperonin is also used for the 10-kDa co-chaperone of the HSP60 family. In this case, the HSP60 family and 10-kDa co-chaperone are called chaperonin 60 (Cpn60) and 10 (Cpn10), respectively.
<i>GroEL</i>	The HSP60 family member protein contained in <i>Escherichia coli</i> and related bacterial species.
<i>Group II archaeobacterial chaperonins</i>	The HSP60 family member proteins contained in archaeobacterial species.
<i>Heat shock proteins (HSPs)</i>	Proteins induced by heat shock and related stress.
<i>HSP60 (60-kDa heat shock protein)</i>	The HSP60 family member protein distributed in mitochondria.
<i>Molecular chaperone</i>	A group of proteins that associate with unfolded proteins and assist in their folding.
<i>Protein folding</i>	The process by which newly synthesized polypeptides or denatured proteins produce functional conformations.
<i>Rubisco subunit binding protein</i>	The HSP60 family member protein distributed in plastids.

Introduction

Heat shock proteins (HSPs) are a group of proteins induced by heat shock and related stress including heavy metals and amino acid analogs. Most HSPs were named according to their molecular mass in kilodaltons with the abbreviation HSP (such as HSP90, HSP70, and HSP60) in mammals. Proteins in the HSP60 family (also called the chaperonin family) form large complexes composed of subunits of approximately 60 kDa. Each complex contains 14–18

subunits and shows a double doughnut-like structure. HSP60 family proteins act as molecular chaperones, assisting in refolding of proteins denatured by heat and related stress and in folding of newly synthesized polypeptides. These proteins were found to be distributed in all organisms investigated to date and in most compartments of eukaryotic cells, including the cytosol, nucleus, mitochondria, and chloroplast. The ubiquitous distribution and chaperone activity of the HSP60 family proteins indicate that the HSP60 family proteins play fundamental roles in the survival of organisms by mediating production and recovery of functional conformations of proteins in the cell.

Members of the HSP60 Family

The HSP60 family includes GroEL of eubacteria, HSP60 of mitochondria, Rubisco subunit binding protein of plastids, the chaperonin containing TCP-1 (CCT, also called TRiC or c-cpn) of eukaryotic cytosol and nucleus, and archaeobacterial chaperonins (e.g., TF55/56, thermosome). These proteins can be divided into two groups based on the amino acid sequence homology and structural similarities (Table 1). GroEL, HSP60, and Rubisco subunit binding protein are classified as group I, while CCT and archaeobacterial chaperonins are classified as group II. GroEL is a major heat-inducible protein of *Escherichia coli* and plays a fundamental role in the stress response by assisting in the refolding of denatured proteins. GroEL is also important for the folding of newly synthesized proteins. HSP60 assists in refolding of mitochondrial proteins imported from the cytosol across the mitochondrial membrane, or after denaturation by heat and related stress. A considerable level of HSP60 is also found in the cytosol, although roles of the cytosolic HSP60 have not been clarified. Rubisco subunit binding protein mediates folding of ribulose-1,5-bisphosphate carboxylase/oxygenase

Table 1 Characteristics of HSP60 family proteins^a

	Organism	Localization	Amino acid identity with		Rotational symmetry	Subunit species	Inducibility by stress
			GroEL	CCT			
Group I							
GroEL	Eubacteria	Soluble	–	<20%	7	1	+
HSP60	Eukaryotes	Mitochondria	60%	<20%	7	1	+
RSBP ^b	Plants	Plastids	60%	<20%	7	2	+
Group II							
CCT (TRiC, c-cpn)	Eukaryotes	Cytosol and nucleus	<20%	–	8	8–9	+
TF55/56	Archaeobacteria	Soluble	<20%	40%	9	3	+
Thermosome	Archaeobacteria	Soluble	<20%	40%	8	2	+

^aMKKS and BBSIO show very weak homology to HSP60 family proteins.

^bRubisco subunit binding protein.

(Rubisco) in plastids. CCT is known to assist in the folding of newly synthesized actin, tubulin, and some other proteins in eukaryotic cytosol and is composed of eight different subunit species encoded by independent genes. Archaeobacterial chaperonins are the major heat-inducible proteins and bind denatured proteins, although they do not always show refolding activity. Recently, a gene encoding novel mammalian chaperonin-like protein was discovered by chromosome mapping for the McKusick–Kaufman syndrome (MKKS) gene. The MKKS gene was also found to be the sixth locus for Bardet–Biedl syndrome (BBS6). The amino acid sequence of MKKS shows a weak identity to those of group II subfamily members. Although this protein distributes in the cytosol with a highly concentrated distribution in the centrosome when overexpressed in mammalian cells, its function and stress inducibility have not been determined. Very recently another BBS gene product (BBSIO) was found to show very weak identity to the HSP family, although no experimental information is currently available for the BBSIO protein.

Response to Heat Shock and Related Stress

GroEL is required during normal and stress conditions for the survival of *E. coli*. Expression of GroEL in *E. coli* is strongly induced by a variety of stressors such as heat shock, ethanol shock, heavy metals, and amino acid analogs. These treatments cause denaturation of proteins in the bacteria, and the denatured proteins require help from molecular chaperones to recover functional conformations. The heat shock response of GroEL is mediated by a transcription factor called σ_{32} , which is the product of the *RpoH* gene. The translation of σ_{32} becomes more efficient at higher temperatures by structural changes of its mRNA, and the translated protein transiently becomes more stable after heat shock. The activity of σ_{32} is inhibited by GroEL but not by substrate-occupied GroEL, suggesting the presence of a transcription factor–chaperone network for sensing and controlling protein folding environment *in vivo*.

Mammalian HSP60 is constitutively expressed under normal conditions and upregulated under stress conditions. Heat shock and related stress induce HSP60 expression, and this response is regulated by a family of transcription factors called heat shock factors (HSFs) through the heat shock elements (HSEs) in the HSP60 gene promoter. In vertebrates, four members of this family (HSF1–4) are known, and HSF1 plays the most important role in controlling the heat shock response. HSF1 is activated by heat shock and related stress, and the HSF1 activity is controlled by

HSP70 and HSP90 by monitoring the protein folding environment at least in part.

CCT is expressed at a basal level under normal growth-arrested conditions such as terminally differentiated cells *in vivo*. CCT expression is upregulated by growth stimulation. For example, CCT is highly expressed in embryos, tumors, and rapidly growing cultured cells. Under the rapidly growing conditions, CCT expression is upregulated by transcription factors whose expression and activity are highly dependent on growth stimulation. In addition, CCT is highly expressed in tissues that are abundant in substrate proteins. CCT expression is particularly high in testis to assist in the folding of tubulin, a major component of sperm tail. CCT is further induced by chemical stress including arsenite and proline analog treatments. As CCT gene promoters contain HSE-like sequences that are recognizable by HSF1 and HSF2, these factors may play a role in the chemical stress-induced expression of CCT. In contrast, CCT was not induced by heat shock as far as investigated. Thus, the mechanism of stress-induced regulation of CCT expression is probably somewhat different from that of typical HSPs.

In several archaeobacterial species, chaperonins become the most major protein under stress conditions. This is considered to be due to severe environmental conditions. For example, thermophilic species grow at temperatures above 80°C.

Function in Protein Folding

The major contribution of HSP60 family proteins in the stress response is to assist in refolding denatured proteins. All the members bind denatured proteins but do not bind functional proteins that are completely folded. Most members of this family show ATPase activity and use it to obtain conformational changes that allow these proteins to release target proteins. Activity of group I members is modulated by co-chaperones of approximately 10 kDa, such as GroES and cpn-10, although homologs of the co-chaperone for group II members are not known. All HSP60 family members have back-to-back stacked double-ring-like structure composed of 14–18 subunits, although rotational symmetry differs between group I and II: group I members show sevenfold symmetry whereas group II members show eight- or ninefold symmetry. Denatured substrate protein is trapped in the central cavity of these cylinder-like molecules near their opening in the absence of ATP. In the case of GroEL, ATP and GroES are bound to the cylinder following trapping substrate. GroES acts as a lid of the GroEL cylinder, and the substrate is encapsulated in the GroEL–GroES cage. In this protected environment, the single substrate

protein is allowed to fold properly without forming nonproductive aggregation. After ATP hydrolysis, the GroES lid and folded substrate are released from the GroEL cylinder. In contrast, group II members including CCT and archaeobacterial chaperonins are able to produce cage-like structures for encapsulating substrate proteins in the absence of GroES-like co-chaperones.

The HSP60 family proteins are considered to cooperate with other molecular chaperones such as HSP70 and HSP40 (DnaJ homolog) family proteins. The HSP60 family proteins also play important roles in the folding of newly synthesized proteins with other molecular chaperones and co-chaperones. In this view, *E. coli* strains overexpressing GroEL can be used to produce some recombinant proteins efficiently.

Medical Aspects

It is known that HSP60 homologs in mycobacteria and related species are highly antigenic in mammals. Immune responses to these proteins and/or HSP60 itself are considered to be involved in several diseases mediated by the immune system, including reactive arthritis, juvenile chronic arthritis, rheumatoid arthritis, Lyme disease, Bechet's disease, systemic lupus erythematosus and insulin-dependent diabetes mellitus.

Recently, SPG13, a dominant human gene responsible for hereditary spastic paraplegia, was mapped to the gene encoding mitochondrial HSP60. Hereditary spastic paraplegia is a genetically heterogeneous neurodegenerative disorder characterized by progressive spasticity and weakness of lower limbs. HSP60 carrying the V72I mutation that is found in the patient group cannot compensate for the function of GroEL when expressed in *E. coli*, whereas wild-type HSP60 can. These observations suggest that the chaperone function of HSP60 plays an important role in preventing diseases caused by protein misfolding, including neurodegenerative disease.

Although exact function of MKKS protein is unknown, its weak homology to the HSP60 family suggests that a particular function may be shared between MKKS and the HSP60 family proteins. Mutations in the MKKS gene cause human developmental anomalies including vaginal atresia with hydrometrocolpos, polydactyly, and congenital heart defects. MKKS also causes BBS, and provides more severe symptoms when mutated together with other BBS genes. BBS is a genetically heterogeneous disorder characterized by obesity, retinal dystrophy, polydactyly, mental retardation, renal malformations, and hypogenitalism. MKKS knockout mice show BBS-like phenotypes including retinal degeneration, failure of sperm flagella formation, photoreceptor

degeneration, obesity, and deficits in olfaction and social dominance. As MKKS and some BBS proteins are highly concentrated in the centrosome and/or basal body of cilia, MKKS protein function may be related to the activity of these organelles and may work together for this activity. It is also possible that MKKS protein functions in protein transport, as suggested for other BBS proteins. As recently identified BBS10 also shows weak homology to the HSP60 family proteins, the function of this BBS protein may be related to that of MKKS.

Glossary

Heat shock gene

Microarray

A gene inducible by heat shock or any other stressor; also called stress gene.

A miniaturized collection of samples (e.g., cDNA made from the mRNAs present in a cell under specific experimental conditions), anchored in a predetermined spatial order to many microareas delimited on a support (e.g., microchip, glass slide, filter, or silicon wafer); this makes the samples available for reaction (e.g., cDNA–DNA hybridization) in a high-throughput mode with known, labeled probes (e.g., DNA with sequences of known genes).

Messenger ribonucleic acid (mRNA)

A molecule composed of bases in a sequence complementary to that of the coding region of a gene; it has the message to synthesize the protein encoded in the gene.

Protein

A molecule formed by amino acids in a sequence dictated by the sequence of bases in the corresponding mRNA.

Ribosome

A large, multimolecular structure present in the cytoplasm of all cells at which protein synthesis takes place according to the message encoded in the mRNA.

Stressor

An agent, which can mechanical, physical, psychological, or chemical, capable of causing cell stress and inducing a stress (heat shock) response. Although the term heat shock response may be used as synonym of stress response, it is more properly applied only to stress responses caused by the stressor heat.

Systems biology

Large-scale, computer-assisted analyses of genomic and proteomics data to elucidate intra- and intercellular gene and protein interactions as they might occur *in vivo*. The purpose of such analyses is ultimately to provide mathematical models and simulations of cellular pathways and networks and of their dynamics. An example is the pathways followed by each chaperoning system and the networks formed by two or more of these systems between them and/or between them and protein-degrading systems so as to maintain intracellular protein homeostasis.

Transcription

The process of synthesis of the mRNA, marking the initial main step of gene expression.

Transcriptome

The whole suite of mRNAs that can be transcribed from a genome; also, more specifically, the subset of mRNAs that are transcribed from a genome of a particular cell (or organism or tissue), at any given time, under specific conditions, for example, under conditions of cell stress

Translation

or under basal, constitutive conditions (no stress).

The process of synthesis of a protein molecule on the ribosome, in which amino acids are linked in a linear non-branching chain that follows the order encoded in the corresponding mRNA.

Heat Shock and Stress

A heat shock response consists of the series of events occurring in a cell that are induced by heat stress (i.e., a sudden temperature elevation) and that reflect the cell's perturbed status compared with the status prior to the stressor's impact. Among all such events, only a few are considered in this article, whose focus is intracellular proteins produced by stress-inducible genes and the phenomena mediated by these proteins.

Many stressors other than a sudden increase in temperature can cause virtually the same series of events as does heat shock. Such cellular reactions are also called heat shock responses for historical reasons. To avoid confusion, the term stress response should be used regardless of the stressor, and the stressor should be mentioned in all cases. Examples of common cell stressors are listed in [Table 1](#). In this article, the expressions stress response, stress gene, and stress protein are preferred over heat shock response, heat shock gene, and heat shock protein, respectively.

Definition

The shock (or stress) produced on an object by an abrupt temperature elevation is called heat shock or

heat stress. Shock and stress are considered synonyms within the context of this article and may be defined as the impact – and its consequences – of an agent, such as heat, on an object. Stress is a perturbed status of the object generated by the impacting agent. The object may be inanimate (e.g., a piece of metal) or living (e.g., a cell or an organism made up of one or more cells). This article deals chiefly with cell stress.

Scope

Stress may be defined more specifically from several different standpoints, depending on the natures of the object and the stressor and on the particular field of knowledge being considered, materials, physical, mechanical, psychological, physiological, or medical sciences, just to name some representative examples.

This article deals with cellular stress caused by heat shock, or heat stress, and by other stressors that produce very similar effects, pertaining to biology in its broadest sense – that of all living organisms, whether uni- or multicelled. If the organism is unicelled, cellular and organismal stresses are synonymous. An illustrative list of organisms that have been used to study the stress response is in [Table 2](#).

It must be borne in mind that although the effects of stressors on the cell are, on the whole, not specific, there are details of the cell's response to stress that vary according to the stressor.

Events

The stress response manifests itself in diverse cellular changes that affect many of the cell's components and properties, from gross morphology to the most

Table 1 Examples of cell stressors^a

Type/group	Name/description
Physical	Heat (including fever), cold, irradiation (e.g., ultraviolet rays), magnetic fields
Mechanical	Compression, shearing, stretching
Nutritional	Starvation: multiple, specific (carbon, glucose, nitrogen, phosphate, nitrate)
pH	Alkalosis, acidosis, pH shift
Osmotic	Changes in the concentration of salt, sugars, other osmolytes (hyper- and hypoosmotic shocks)
Antibiotics	Puromycin, tetracycline, nalidix acid
Alcohols	Ethanol, methanol, butanol, propanol, octanol
Oxygen	Oxygen-derived free radicals (ROS), hydrogen peroxide, anaerobiosis to aerobiosis shift (e.g., reperfusion), hypoxia/anoxia (ischemia)
Biological	Infection, inflammation, fever
Psychological	Emotions, conflicts; hormonal imbalance (HPA axis, autonomic nervous system)
Metals	Cadmium, copper, chromium, zinc, tin, aluminum, mercury, lead, nickel
Other	Desiccation, benzene and derivatives, phenol and derivatives, teratogens, carcinogens, mutagens, arsenite, arsenate, amino acid analogs, nicotine, anesthetics, insecticides, pesticides

^aThese agents cause stress not only in human and other (e.g., mouse and rat) eukaryotic cells but also in prokaryotic (e.g., bacterial) cells. HPA, hypothalamic-pituitary-adrenal; ROS, reactive oxygen species. Modified from Macario, A. J. L. and Conway de Macario, E. (2000), Stress and molecular chaperones in disease, *International Journal of Clinical and Laboratory Research* **30**, 49–66, with permission from the copyright owner.

Table 2 Examples of organisms whose cells and tissues have been used as experimental models to study cell stress and the stress (heat shock) response

Type	Name
Prokaryote	
Bacterium	<i>Agrobacterium tumefaciens</i> , <i>Anabaena</i> sp., <i>Bacillus subtilis</i> , <i>Borrelia burgdorferi</i> , <i>Bradyrhizobium japonicum</i> , <i>Campylobacter jejuni</i> , <i>Clostridium acetobutylicum</i> , <i>Escherichia coli</i> , <i>Lactococcus lactis</i> , <i>Rhodothermus obamensis</i> , <i>Shewanella oneidensis</i> , <i>Staphylococcus aureus</i> , <i>Streptomyces coelicolor</i> , <i>Syneccoccus</i> sp.
Archaeon	
Methanogen	<i>Methanosarcina mazei</i> , <i>Methanosarcina thermophila</i> , <i>Methanococcus voltae</i>
Extreme halophile	<i>Halobacterium halobium</i> , <i>Haloferax volcanii</i>
Thermophile	<i>Thermoplasma acidophilum</i>
Hyperthermophile	<i>Archaeoglobus fulgidus</i> , <i>Pyrodictium occultum</i> , <i>Sulfolobus shibatae</i>
Eukaryote	
Unicelled	<i>Arxiozyma telluris</i> , <i>Mrakia frigida</i> , <i>Saccharomyces cerevisiae</i> (yeasts) <i>Tetrahymena thermophila</i> (protozoan) <i>Euglena gracilis</i> (alga)
Multicelled	<i>Neurospora crassa</i> (fungus) <i>Schistosoma mansoni</i> , <i>Caenorhabditis elegans</i> (worms) <i>Crassostrea gigas</i> (oyster) <i>Drosophila melanogaster</i> (insect) <i>Salmo gairdnerii</i> [rainbow trout], <i>Danio rerio</i> [zebrafish] (fishes) <i>Arabidopsis thaliana</i> [wall cress], <i>Lycopersicon esculentum</i> [tomato] (plants) <i>Gallus gallus</i> [chicken] (bird) <i>Mus musculus</i> [mouse], <i>Rattus norvegicus</i> [rat], <i>Meriones unguiculatus</i> [gerbil], <i>Homo sapiens</i> [human] (mammals)

detailed biochemical and molecular mechanisms. A list of cellular components and properties affected by stressors such as heat shock and the methods used to study the cell's response or reaction to stressors are shown in [Table 3](#).

Characteristics

The stress response is characterized by a decrease in the levels of many proteins and a concurrent increase in the levels of others. In addition, a series of proteins appear that were not detectable prior to the stressor's impact. The proteins that increase or appear as a consequence of stress are the stress proteins. The subset of these proteins that are the product of genes induced by heat shock are called heat shock proteins (Hsps). However, for historical reasons the same name Hsp is also used to designate proteins encoded in genes that are inducible by any stressor. An illustrative sample of stress proteins, including Hsps, is presented in [Table 4](#). In this table, some molecules (thermoprotectants) that are not proteins but that, like the stress proteins, function to counteract the effects of stressors are also mentioned. These nonproteinic antistress compounds are mentioned to convey the idea that the cell possesses a variety of antistress mechanisms beyond the stress proteins and also to draw attention to

the fact that all the proteins (e.g., enzymes) that participate in the production and trafficking of these antistress compounds must work during the stress response and that, therefore, they are part of the antistress mechanisms, too.

Mechanisms

Many genes are downregulated or shut off as a consequence of stress. If the affected genes are ones that produce proteins, their protein products decrease or disappear. In contrast, other genes are upregulated or induced *de novo* by stress. These are the heat shock or stress genes *sensu lato*. Among them, there is a group that belongs to the category of protein producers. Their products are the heat shock or stress proteins, some of which are important for cell survival during stress and for cell recovery after stress. A subset of heat shock proteins are molecular chaperones; they assist other proteins to fold correctly during synthesis and to refold if they have been partially denatured by stress. One of the best-known molecular chaperones is the stress protein Hsp70(DnaK), which interacts with at least two others, Hsp40 (DnaJ) and GrpE in prokaryotes (or BAG-1, or HspPB1 in eukaryotes), to bring about protein folding or refolding.

Table 3 Cellular components and properties affected by heat shock and methods used to study the stress (heat shock) response of the cell

<i>Component / property</i>	<i>Method</i>
Viability, growth rate	Cell counts
Morphology (size; shape; formation of multicellular structures or spores)	Various types of light and electron microscopies Biochemical and immunochemical analyses of cell envelopes and intercellular connective materials Histochemistry Immunohistochemistry
Proteins	
General contents	One- and two-dimensional electrophoresis
Synthesis, general	Incorporation of radioactively labeled amino acids followed by quantification of radioactive fractions resolved by electrophoresis or other fractionation methods (e.g., chromatography) DNA microarray-proteomics (two-dimensional electrophoresis plus other methods, e.g., western blotting, mass spectrometry, microsequencing) to determine the exact nature of the proteins synthesized in response to stress Two-hybrid method to detect protein-protein interactions followed by bioinformatics (systems biology, neural networks)
Synthesis, specific	Separation and/or quantification of target stress proteins using specific antibodies (immunoprecipitation, western blotting) Identification of protein complexes by electron microscopy combined with immunochemistry and functional assays (e.g., determination of ATPase activity and capacity to assist protein folding or refolding) Microsequencing
Genes ^a	Measurement of transcript (mRNA) for stress proteins: quantity, size (length), transcription initiation and termination sites (northern blotting, primer extension, S-1 nuclease protection, reverse PCR) DNA microarray-transcriptomics and proteomics (two-dimensional electrophoresis plus other methods, e.g., northern and western blottings, mass spectrometry, microsequencing) to determine the exact nature of the proteins synthesized in response to stress and, thus, identify genes involved Systems biology, neural networks

^aPresence or absence of genes is determined by genome sequencing; cloning and sequencing; and Southern, northern, and western blottings. PCR, polymerase chain reaction.

Table 4 Some stress (heat shock) proteins proven or believed to play a role during the stress (heat shock) response and in cell recovery after stress^a

<i>Group</i>	<i>Examples</i>
1	Molecular chaperones and chaperonins, Hsp70(DnaK), Hsp40(DnaJ), GrpE, GroEL, GroES, Hsp90, Hsp104, sHsp
2	Regulators of stress (heat shock) genes: sigma factors (e.g., σ^{32} , σ^E , σ^B), positive regulators or activators (e.g., HSF), negative regulators (e.g., HrcA, HspR)
3	Proteins that constitute the intercellular connective material of multicellular structures formed as a response to stress
4	Transport proteins: e.g., archaeal TrkA
5	Proteases: Clp family, Lon/La, HtrA, proteasome components
6	Enzymes and cofactors involved in the synthesis of other stress proteins (listed in the preceding groups 1–5) and other molecules, such as thermoprotectants (trehalose; di- <i>myo</i> -inositol phosphate; cyclic diphosphoglycerate)
7	All proteins, enzymes, cofactors, and gene-regulatory factors involved in sporulation

^aHSF, heat shock factor; Hsp, heat shock protein. Modified from Macario, A. J. L. and Conway de Macario, E. (2000), Stress and molecular chaperones in disease, *International Journal of Clinical and Laboratory Research* **30**, 49–66, with permission from the copyright owner.

A balanced set of proteins, each in its native functional conformation and at its physiological concentration, is key to cell survival. Heat shock and other stresses alter the cellular proteins. These tend to lose their functional shapes; they denature. Protein
